We introduce *TextSeal*, a state-of-the-art watermark for large language models. Building on Gumbel-max sampling, TextSeal introduces dual-key generation to restore output diversity, along with entropy-weighted scoring and multi-region localization for improved detection. It supports serving optimizations such as speculative decoding and multi-token prediction, and does not add any inference overhead. TextSeal strictly dominates baselines like SynthID-text in detection strength and is robust to dilution, maintaining confident localized detection even in heavily mixed human/AI documents. The scheme is theoretically distortion-free, and evaluation across reasoning benchmarks confirms that it preserves downstream performance; while a multilingual human evaluation (6,000 A/B comparisons, 5 languages) shows no perceptible quality difference. Beyond its use for provenance detection, TextSeal is also “radioactive”: its watermark signal transfers through model distillation, enabling detection of unauthorized use.

Meta

1 Introduction

The rapid adoption of LLMs in production systems has created a need for reliable provenance mechanisms. Watermarking, by embedding an imperceptible, algorithmically-detectable signal during the generation, addresses several needs at once: detecting AI-generated content, complying with regulations that mandate machine-detectable marking of AI outputs (Eur, 2024; European Commission, 2026), and enabling applications such as monitoring model output usage, preventing self-training on generated data, and detecting unauthorized distillation (Sander et al., 2024; Sablayrolles et al., 2020).

For production deployment, it is highly desirable to use *distortion-free* watermarking, which ensures that next-token selection follows exactly the same distribution as that produced by the LLM. It pre-

Figure 1 TextSeal achieves state-of-the-art detectability while preserving generation diversity and downstream performance (Qwen3.5-72B). (a) TextSeal strictly dominates SynthID across the diversity-detectability frontier (ELI5, 400 tokens, $T=0.8$, top- $p=0.9$). (b) Localized detection remains confident even at 10 $\times$ dilution, where global baselines fail. (c) Accuracy across 12 benchmarks is preserved ($T=0.6$).

serves the exact decoding configuration (temperature, top- p) the model was tuned for, embedding the watermark at zero cost to any individual generation’s quality. A recent large-scale comparison (Fernandez et al., 2025) shows that the Gumbel-max watermark (Aaronson and Kirchner, 2023) achieves the best detectability-quality Pareto frontier by far among other methods, e.g., green-red list (Kirchenbauer et al., 2023a), SynthID (Dathathri et al., 2024), DiPMark (Wu et al., 2023). However, Gumbel-max has one important drawback: it is fully *deterministic* (a fixed prompt and secret key always produce the same output, eliminating diversity), which can in turn trigger degenerate loops when repeated n-grams used for hashing cause the pseudo-random function to lock onto the same token (Remark 1). For instance, SynthID (deployed in Google’s Gemini) resolves the determinism while remaining distortion-free, with a tournament-sampling design.

TextSeal is a distortion-free, non-deterministic watermark for LLMs. It builds upon the Gumbel-max framework and introduces three core improvements:

1. **Dual-Key Generation:** We overcome determinism by randomly alternating between two secret keys during generation, restoring diversity at low cost to detection power. This natively supports speculative decoding and Multi-Token Prediction (MTP) without additional latency (subsection 3.1).
2. **Entropy-Weighted Detection:** We introduce tests tailored to the dual-key generation, that may leverage the entropy of a proxy model, and moment-matched Gamma approximations to have calibrated p -values (subsection 3.2).
3. **Localized Detection:** We identify individual watermarked segments within a document via a multi-region geometric cover search, dramatically boosting detection under dilution (subsection 3.3).

As summarized in Figure 1, TextSeal achieves state-of-the-art detectability while offering a superior diversity-detectability trade-off compared to existing methods. Our localized detection is robust to dilution within long documents, and TextSeal preserves the downstream capabilities of the model across 12 complex benchmarks. TextSeal adds only $\leq 0.3\%$ sampling overhead ($3\times$ faster than SynthID; subsection 5.4). Beyond provenance, TextSeal is *radioactive* (Sander et al., 2024; Sablayrolles et al., 2020): the watermark signal transfers through model distillation, meaning that a student model trained on watermarked outputs inherits a detectable trace. This provides a practical safeguard against unauthorized distillation and enables monitoring of how model outputs are used downstream (in training pipelines, RAG systems, or by competitors). We demonstrate this experimentally in section 6.

The paper is organized as follows. Section 2 presents the technical background on Gumbel-max watermarking. Section 3 describes the TextSeal method. Section 4 presents the main experimental results. Section 5 provides ablation studies and additional analyses. Section 6 demonstrates watermark transfer through distillation.

2 Background and Related Work

2.1 LLM Watermarking

Early text watermarking relied on edit-based methods (Topkara et al., 2005, 2006c) with low robustness. For LLMs, two concurrent approaches appeared after ChatGPT: green-red list biasing (Kirchenbauer et al., 2023a) and Gumbel-max sampling (Aaronson and Kirchner, 2023), both using pseudorandom seeds from a secret key and preceding tokens, enabling lightweight detection without access to the model. Some subsequent work explores multi-bit watermarking (Fernandez et al., 2023; Yoo et al., 2024; Qu et al., 2024), undetectable constructions (Christ et al., 2023; Kudipudi et al., 2023), low-entropy optimizations (Lee et al., 2023; Huang et al., 2023), semantic watermarks (Liu et al., 2023; Liu and Bu, 2024; Hou et al., 2023), adaptive green-red variants (Wang et al., 2025), distillation for open-weights model (Gu et al., 2023), etc. See subsection A.3 for detailed scheme descriptions. Beyond detection, watermark radioactivity (Sander et al., 2024) has been leveraged for data protection (RAG (Jovanović et al., 2025), contamination (Sander et al., 2025), copyright (Zhang et al., 2025)), which we extend in section 6 to reasoning-trace distillation.

2.2 Distortion-Freeness and Choice of Baselines

In the literature on LLM watermarking, schemes are typically divided into two families: *distortionary* (biased) and *distortion-free* (unbiased/distribution-preserving). The key distinction is whether the watermark alters text quality. A watermarking scheme is distortion-free if the embedding process exactly preserves the model’s next-token distribution. More formally, after marginalizing over the uniformly sampled secret key $K \in \mathcal{K}$, the probability of generating any token v at step t matches the base model probability $p_v^{(t)}: \mathbb{E}_{K \sim \mathcal{K}} [\mathbb{P}(\text{output}_t = v \mid \text{context}, K)] = p_v^{(t)}, \quad \forall v \in \mathcal{V}$. Thus, each token is sampled from the original LLM distribution, implying no quality degradation.

To achieve this, distortion-free methods replace standard stochastic sampling with a pseudorandom process determined by the secret key and the previous context. As a result, although marginal token probabilities remain unchanged, sequence-level diversity is reduced: repeated generations with the same prompt and key become strongly correlated compared to ordinary temperature sampling.

Green-red list (Kirchenbauer et al., 2023a) and low-entropy filtering methods, like SWEET (Lee et al., 2023) which skips watermarking on low-entropy tokens, are *not* distortion-free: they shift the output distribution, degrading generation. MorphMark (Wang et al., 2025) adaptively scales the green-red bias based on the natural green-list probability mass, reducing distortion in low-entropy contexts, but remains non-distortion-free since it still applies a logit bias. Semantic watermarks (Liu et al., 2023; Liu and Bu, 2024; Hou et al., 2023) require auxiliary semantic encoders, making them harder to deploy. Gumbel-max (Aaronson and Kirchner, 2023), Permute-and-Flip (Zhao et al., 2024), DiPMark (Wu et al., 2023) (distortion-free green-red via pseudorandom permutations), SynthID-Text (Dathathri et al., 2024) (deployed in Google Gemini), and WaterMax (Giboulot and Furon, 2024) (multiple generations per query, impractical for production) are distortion-free methods. Aligned with recent large-scale evaluations (Fernandez et al., 2025), we found that Gumbel-max and SynthID achieved the best detectability-quality Pareto frontier. We therefore compare TextSeal against these two practical baselines. Because all three are distortion-free, we can fix the LLM, temperature, and top- p , and vary only their watermark-specific diversity parameter, isolating the watermark’s effect.

2.3 Gumbel-Max Watermarking

We consider a language model generating a sequence of tokens. At each time step t , the model predicts a probability distribution $\mathbf{p}^{(t)} = (p_1, \dots, p_{|\mathcal{V}|})$ over the vocabulary $\mathcal{V}$. Let K be a secret key used for watermarking and h_t the context (history of tokens) at step t . The goal of watermarking is to select a token x_t such that its selection is statistically correlated with a pseudo-random value derived from h_t and K , while preserving the original distribution $\mathbf{p}$ (distortion-free). This concept was introduced for LLMs by Aaronson and Kirchner (2023) with the Gumbel-max scheme.

2.3.1 Gumbel-max mechanism

The standard Gumbel watermarking ensures detectability by making the sampling process deterministic given the secret key and watermark context (see App. Fig 10 for an overview).

Embedding. At each generation step t , the watermark operates on a *watermark context window* $\mathbf{w} = (x_{t-k}, \dots, x_{t-1})$, consisting of the k last generated tokens. This window, together with the secret key K , seeds a Pseudo-Random Function (PRF) that assigns a pseudo-random value $R_v \in [0, 1]$ to every candidate token v in the vocabulary:

$$R_v = \text{PRF}(v, \mathbf{w}, K).$$

The PRF is deterministic: for a given context window, secret key, and candidate token, it always returns the same value. However, its output is indistinguishable from uniform randomness to anyone who does not know K (see subsection A.1 for implementation details of the PRF).

The watermark then selects the next token by combining these pseudo-random values with the LLM’s probability distribution. Concretely, it picks:

$$x_t = \arg \max_{v \in \mathcal{V}} R_v^{1/p_v^{(t)}},$$

where $p_v^{(t)}$ is the probability assigned to token v by the LLM at step t . This balances two factors: tokens with high model probability p_v are naturally favored, but among tokens of similar probability, the one with the highest PRF value R_v wins. This creates a statistical correlation between the chosen tokens and the secret key, which can later be detected.

This selection rule is equivalent to two well-known sampling schemes:

- **Inverse Transform Method:** Sort tokens by descending probability, compute the CDF, and select the token corresponding to the quantile $u = \text{PRF}(\mathbf{w}, K)$.
- **Gumbel-Max Trick:** Sample Gumbel noise $G_v = -\log(-\log(R_v))$ for each token and select $x_t = \arg \max_v (G_v + \log p_v^{(t)})$.

Put differently, the watermarking scheme samples from the original distribution $\mathbf{p}$, but uses a deterministic source of randomness derived from the secret key and context, instead of true randomness. This is what gives it the distortion-free property, as formalized in [Proposition 1](#) below.

Detection. Given a text, the detector re-computes the PRF values using the secret key and the preceding tokens, then checks whether the score is higher than expected by chance.

We denote by $x^{(1)}, \dots, x^{(T)}$ the sequence of tokens in the text, and by $\mathbf{R}^{(t)} \in [0, 1]^{|V|}$ the key random vector re-computed from the k preceding tokens and the secret key. We define $R_t := R_{x^{(t)}}^{(t)}$, the PRF value of the token selected at time-step t . The detection score is calculated as:

$$S_T = -\sum_{t=1}^T \ln(1 - R_t).$$

Intuitively, watermarked tokens tend to have high R_t values (since the selection rule favors them), making $-\ln(1 - R_t)$ large. For unwatermarked text, R_t values are essentially random, yielding a lower score. A statistical test then determines whether the observed score is significantly higher than expected under the null hypothesis $\mathcal{H}_0$ (no watermark). In practice, we choose a threshold τ (depending on the desired false positive rate) and flag a text as watermarked if $S_T > \tau$.

2.3.2 Theoretical Properties

The following results formalize the two key guarantees of Gumbel-max watermarking: distortion-freeness and detectability. The proofs are not original contributions; they were presented by [Aaronson and Kirchner \(2023\)](#) and formalized by [Fernandez et al. \(2023\)](#). We provide them in [Appendix B](#).

2.3.3 Distortion-Freeness

Proposition 1 (Sampling probability). *Consider a discrete distribution $\mathbf{p} = (p_1, \dots, p_V)$ and $V = |V|$ random variables $\mathbf{R} = (R_1, \dots, R_V)$ s.t. $R_v \stackrel{iid}{\sim} \mathcal{U}_{[0,1]}$. Let $V^* = \arg \max_v R_v^{1/p_v}$. Then:*

$$\mathbb{P}(V^* = v) = p_v.$$

Corollary 1. *Conditionally on $V^* = v$, $R_{V^*} \sim \text{Beta}(1/p_v, 1)$.*

[Proposition 1](#) establishes that the watermark is *distortion-free*: in expectation over the random key, the selected token follows exactly the LLM’s original distribution. The corollary characterizes the distribution of the PRF value for the selected token, which is useful for the detection analysis below.

Remark 1 (Repeated n -grams and strict distortion-freeness). The distortion-free property ([Proposition 1](#)) holds assuming each context window $\mathbf{w}$ appears at most once per key during generation. When the same k -gram context repeats with the same key, the PRF produces identical pseudo-random values, making the selection deterministic rather than stochastic, introducing distortion.

To guarantee strict distortion-freeness for every token within a single generation, one must maintain a set $\mathcal{S}$ of seen context windows *for that generation* and apply the following protocol ([Dathathri et al., 2024](#)):

1. **First occurrence** of a context window: watermark with a randomly chosen key (as in standard dual-key routing) and record the window and key used in $\mathcal{S}$.
2. **Second occurrence**: the first key is exhausted, so watermark with the other key and record it in $\mathcal{S}$.
3. **Third occurrence and beyond**: both keys are exhausted for this window; fall back to standard unwatermarked sampling.

Dual-key routing thus doubles the number of watermarkable slots per context window compared to single-key schemes before any fallback is needed. The memory overhead of $\mathcal{S}$ is negligible (one hash per generated token), but the implementation requires stateful tracking within each generation call. Our main evaluations do not enforce this protocol (except in [subsection E.1](#)), as repeated k -grams are rare in practice with $k \geq 3$.

2.3.4 Detectability

Proposition 2 (*p-value under $\mathcal{H}_0$*). *Under $\mathcal{H}_0$ (text not watermarked), the score S_T follows a $\Gamma(T, 1)$ distribution. The p-value associated to a score s is:*

$$p\text{-value}(s) = \mathbb{P}(S_T > s \mid \mathcal{H}_0) = \frac{\Gamma(T, s)}{\Gamma(T)}, \quad (1)$$

where $\Gamma(T, s)$ is the upper incomplete gamma function.

This provides an *exact* false positive rate: given any desired significance level α , we can compute a detection threshold τ such that the probability of wrongly flagging unwatermarked text as watermarked is exactly α .

Proposition 3 (*Expected score under $\mathcal{H}_1$*). *Under $\mathcal{H}_1$ (text is watermarked), $\mathbb{E}(S_T) \geq T + \left(\frac{\pi^2}{6} - 1\right) H_T$,*

where $H_T = -\sum_{t=1}^T p_t \ln(p_t)$ is the entropy of the completion.

This bound reveals that detectability scales with the entropy of the generated text. When the LLM is uncertain (high entropy), many tokens have non-negligible probability, giving the watermark more room to influence the selection and producing a stronger signal. Conversely, when the model is very confident (low entropy), the top token dominates regardless of the PRF values, and the watermark signal is weak. This entropy dependence motivates the entropy-weighted detection of [subsection 3.2](#).

3 Method: TextSeal

TextSeal addresses three key limitations of the standard Gumbel-max watermark: its deterministic outputs, its suboptimal detection in mixed-entropy text, and the lack of localized detection capability. We describe each improvement below, and present an overview in [Figure 2](#).

3.1 Dual-Key Routing for Diversity and Speculative Decoding

Gumbel-Max is deterministic: for a given context and secret key, the output token is fixed, so re-generating the same prompt always produces identical text, limiting user experience and triggering repetitive loops ([Holtzman et al., 2019](#)). TextSeal addresses this by maintaining two secret keys $k^{(1)}$ and $k^{(2)}$ that restore diversity while preserving both detectability and the distortion-free property.

Embedding. At each generation step t , one key is selected at random: $k^{(1)}$ with probability $1 - \alpha$, or $k^{(2)}$ with probability α . The token is produced via Gumbel-Max using the selected key’s PRF:

$$x_t = \arg \max_v R_v^{(k), 1/p_v^{(t)}}, \quad k \in \{k^{(1)}, k^{(2)}\} \quad (2)$$

The routing probability $\alpha \in [0, 0.5]$ controls the diversity-detectability trade-off. Dual-key routing also doubles the tolerance to repeated n -grams before distortion-freeness is compromised ([Remark 1](#)).

Detection. The detector does not know which key generated each token. To capture signal from both potential paths, we compute scores under both keys and aggregate them as a weighted sum:

$$s_i = (1 - \alpha) \cdot s_i^{(1)} + \alpha \cdot s_i^{(2)}, \quad \text{where } s_i^{(j)} = -\ln(1 - R_i^{(j)}) \quad (3)$$

We call this strategy “early fusion”, in contrast with methods that would compute two p-values and aggregate them later. Under $\mathcal{H}_0$, s_i is a weighted combination of independent exponentials with mean 1 and variance $\theta_R = \alpha^2 + (1 - \alpha)^2$. The final p-value is computed using the unified framework in [subsection 3.2](#). We show that this early-fusion approach is better than Fisher or Bonferroni aggregations in [subsubsection C.1.1](#), and support it empirically in [subsection 5.1](#).

Compatibility with speculative decoding. In speculative decoding ([Leviathan et al., 2023](#)), a draft model P_D proposes tokens accepted by a target model P_T . With dual-key watermarking, the draft uses $k^{(1)}$ and rejected correction tokens use $k^{(2)}$. The draft acceptance rate naturally determines the routing ratio α . Since this rate varies by domain and model pair, α can be calibrated at detection time or set to 0.5 as a robust default that makes detection method invariant to the true routing ratio. This extends naturally to Multi-Token Prediction (MTP) ([Gloeckle et al., 2024](#)), where all K auxiliary heads share $k^{(1)}$ and fall back to $k^{(2)}$, preventing the fracturing of statistical power across many keys.

3.2 Entropy-Weighted Detection

Entropy Weighting. When the next-token distribution has low entropy, the top token already has probability close to 1, so the choice is weakly influenced by the PRF value R_v and carries little watermark signal. TextSeal therefore weights each token’s detection score by its local entropy H_i , so that high-entropy positions contribute more to the final statistic. We estimate H_i with a single forward pass of an auxiliary model, e.g., a smaller or quantized model from the same family as the generator.

Figure 2 TextSeal overview. **Left (Embedding):** At each step, one of two keys is randomly selected (probability α for $k^{(2)}$, $1-\alpha$ for $k^{(1)}$), and the token is chosen via Gumbel-Max using the selected key’s PRF ([subsection 3.1](#)). **Right (Detection):** Scores are computed under both keys and fused per-token, weighted by entropy ([subsection 3.2](#)), then a geometric cover search localizes watermarked regions ([subsection 3.3](#)).

Formally, we assign each token-level score s_i an entropy weight w_i^{ent} and compute

$$S_{\text{combined}} = \sum_{i=1}^n w_i^{\text{ent}} \cdot s_i, \quad \text{where } w_i^{\text{ent}} = 0.1 + 0.9 \cdot \frac{H_i - H_{\min}}{H_{\max} - H_{\min}}. \quad (4)$$

where the entropy is normalized within the sequence so the weights span a broad dynamic range regardless of the absolute entropy scale. This attenuates low-entropy tokens instead of letting them dilute the score, while preserving the strongest evidence from uncertain positions. Unlike prior entropy-filtering approaches (Lee et al., 2023) that threshold the entropies, our scheme is continuous: every token still contributes, but with strength matched to its expected usefulness. Since the null statistic is a weighted sum of independent exponentials, the moment-matched Gamma approximation below provides calibrated p -values that explicitly account for these entropy weights.

Moment-Matched Gamma Approximation. S_{combined} is a weighted sum of independent, non-identical exponentials, which follows a hypoexponential whose CDF, while closed-form, is numerically unstable when rates are similar and costly to evaluate for large n .¹ A Gaussian approximation fails to capture the heavy-tailed scores, so we use moment matching instead. Under $\mathcal{H}_0$, each term has mean w_i^{ent} and variance $(w_i^{\text{ent}})^2 \theta_R$. We fit $S_{\text{combined}} \sim \text{Gamma}(k_{\text{new}}, \theta_{\text{new}})$ by matching the first two moments:

$$\theta_{\text{new}} = \theta_R \frac{\sum (w_i^{\text{ent}})^2}{\sum w_i^{\text{ent}}}, \quad k_{\text{new}} = \frac{(\sum w_i^{\text{ent}})^2}{\theta_R \sum (w_i^{\text{ent}})^2} \quad (5)$$

The resulting p -value is

$$p\text{-value}(S_{\text{combined}}) = 1 - F_{\Gamma}(S_{\text{combined}}; k_{\text{new}}, \theta_{\text{new}}) \quad (6)$$

We show in [subsection 5.2](#) that this approximation is well-calibrated under $\mathcal{H}_0$, and in [subsection 5.1](#) that it significantly outperforms unweighted detection. This framework handles dual-key routing (α) and entropy gating (w_i^{ent}) in a single frequentist test.

3.3 Multi-Region Localization and Adaptive Ensemble

When a document contains multiple scattered watermarked regions (e.g., distinct AI-generated paragraphs pasted into a human-written essay), evaluating a global score suffers from two critical flaws. First, the unwatermarked background tokens severely dilute the statistical signal. Second, it fails to identify the specific provenance of individual segments, which is critical for practical attribution.

Geometric Cover Search & Greedy Extraction. To solve this, our goal is to extract a set of disjoint watermarked intervals $\{[a_1, b_1], \dots, [a_y, b_y]\}$. A naive search over all $\mathcal{O}(n^2)$ possible start and end pairs is computationally prohibitive and incurs a massive multiple-testing penalty. Instead, we employ a geometric cover search, reducing the space to dyadic window lengths $L \in \{L_0, 2L_0, 4L_0, \dots, 2^{\lceil \log_2 n \rceil}\}$, sliding each window across the text at half-length offsets. This yields a strictly bounded number of candidate windows, $M \approx 4n/L_{\min}$.

The extraction proceeds in two stages. First, we rank all M windows by their raw score sum (computed in $\mathcal{O}(1)$ per window via prefix sums). Then, for the top candidates only, we compute the rigorous entropy-weighted Gamma p -value. The greedy extraction selects the window with the lowest p -value, flags it as watermarked, masks its tokens, and repeats on the residual text, aggregating intervals as long as their combined significance overcomes the multiple-testing tax. This localized extraction is governed by the minimum zone length $L_{\min}$ (default 50) and the maximum number of zones $Y_{\max}$ (default 5). Full mathematical details are provided in [Appendix D](#).

Adaptive Ensemble Detection. Discovering y regions among M candidates incurs a combinatorial multiple-testing tax. To adapt to any editing behavior, our ensemble selects the most significant among three strategies, applying a flat Bonferroni correction ($k = 3$): (1) **Global** full-text test (no

¹The hypoexponential CDF involves a sum of n exponentials with coefficients $\prod_{j \neq i} \lambda_j / (\lambda_j - \lambda_i)$, which become unstable when rates are close. In contrast, the Gamma CDF reduces to the well-optimized incomplete gamma function.

search penalty), (2) **Single-Best** window (penalized by $\log_{10} M$), and (3) **Multi-Region** aggregation over y zones (penalized by $\log_{10} \binom{M}{y} + \log_{10} Y_{\max}$). The final significance score is:

$$\log_{10} p_{\text{final}} = \min(\log_{10} p_{\text{global}}, \log_{10} p_{\text{single}}, \log_{10} p_{\text{multi}}) + \log_{10} 3 \quad (7)$$

The Dilution Rescue Effect. For largely unedited text, the ensemble gracefully defaults to the global test, paying a negligible worst-case penalty of $\log_{10}(3)$. Consider w watermarked tokens with expected per-token score $\mu > 1$ (as given by [Proposition 3](#)), split into y chunks within a document of length n . Under extreme dilution ($n \gg w$), the global test’s significance drops as its signal-to-noise ratio scales by $\mathcal{O}(w^2(\mu - 1)^2/n)$. The multi-region strategy isolates the pure signal ($\mathcal{O}(w(\mu - 1)^2)$) but pays a combinatorial tax scaling as $\mathcal{O}(y \log_{10} n)$. Localization rescues detection when the isolated signal outpaces this logarithmic tax: $w(\mu - 1)^2 \gtrsim y \log_{10} n$. For instance, $w = 800$ tokens ($\mu = 1.2$) in $y = 5$ chunks easily overcome the $5 \log_{10} n$ tax, allowing confident detection even within $n = 100,000$ tokens—a scenario where the global signal is destroyed.

High-Resolution Boundary Annotation (mIoU). While the greedy ensemble rigorously bounds the False Positive Rate, the harsh combinatorial tax forces it to prematurely discard small fragments, making it suboptimal for exact boundary estimation (mean Intersection over Union, or mIoU). To achieve high-resolution localization, we decouple *detection* from *annotation*. If the ensemble definitively rejects the null hypothesis $\mathcal{H}_0$, we drop the search taxes and apply a localized density smoother. Tokens satisfying a normalized weighted moving average $\bar{S}_i > \tau$ are locally annotated as watermarked, allowing the recovery of fine-grained, sentence-level provenance (see [Appendix D](#) for exact formulation).

4 Main Experiments

4.1 Experimental Setup

Models & Datasets Unless stated otherwise, we use Qwen 3.5-27B ([Qwen Team, 2026](#)) for generation, with $T = 0.8$, top- $p = 0.9$, and reasoning disabled. We evaluate on 1k prompts from the ELI5 dataset ([Fan et al., 2019](#)) (with 5 different seeds), truncating answers to 400 tokens. For entropy-aware detection ([subsection 3.2](#)), we by default use the lightweight Qwen 3.5-0.8B model.

We compare *TextSeal* (default mixing parameter $\alpha = 0.1$ from [subsection 3.1](#)) to *Gumbel-Max* ([Aaronson and Kirchner, 2023](#)) and *SynthID-Text* ([Dathathri et al., 2024](#)) with depth 10. *SynthID-Text* embeds a watermark via multi-layered tournament sampling with binary random functions, and proposes two detection methods: (i) a frequentist Z-test over the mean tournament score, and (ii) a Bayesian detector that estimates the posterior $\mathbb{P}(\text{watermarked} \mid \text{scores})$ via a logistic regression or MLP trained on a representative dataset. We use the frequentist Z-test, because the Bayesian detector provides no controlled false-positive rate, does not generalize across domains (its posteriors depend on the training distribution), and is incompatible with localized multi-window testing (full discussion in [Appendix A.2](#)). We by default fix the watermark context window size to $k = 3$ for all methods, meaning the pseudo-random function depends on the three preceding tokens. At detection time, we deduplicate (context window, token) tuples, because the PRF is deterministic and repeated tuples would yield identical scores, violating the independence assumption of the statistical test ([Fernandez et al., 2023](#)).

4.2 Detectability-Diversity Trade-off

A practical watermark must embed a robust signal without changing the output distribution. For [Figure 1a](#), we vary for *TextSeal* the mixing parameter α from [subsection 3.1](#) from 0 (deterministic) to 0.5 (blue and green curves). For *SynthID*, we vary the depth from 2 to 20. *TextSeal* consistently dominates the detectability-diversity trade-off. Furthermore, using the 27B model for entropy detection (“TextSeal high”) boosts detectability by 1–2 orders of magnitude at higher detection cost.

Table 1 Accuracy across multiple benchmarks with and without *TextSeal* (SQA* = SimpleQA). No significant performance drop is observed across benchmarks, confirming that TextSeal preserves the capabilities of the underlying model.

4.3 Performance on Benchmarks

We evaluate how TextSeal’s watermarking impacts performance across a suite of 12 benchmarks spanning math, code, general knowledge, and common sense domains. We use Qwen 3.5-72B with $T = 0.6$ (mild watermarking) and $T = 1.0$ (stronger watermarking²) and compare against vanilla generation without watermarking. Each benchmark is evaluated with generation at top- $p = 0.95$, reasoning temperatures 0.6 or 1.0 and a maximum reasoning budget of 3,000 tokens.

On average, TextSeal preserves the performance of the underlying model across benchmarks and temperature settings, with no significant differences. However, we observe a slight performance drop on code benchmarks (Human-eval: HE and MBPP) of 1-2 points. Analyzing the outputs suggests that this drop comes from minor formatting omissions rather than incorrect reasoning or algorithmic failures. In particular, all watermarked generations from HE that fail with watermarking and not without fail because they give only the function definition while still using annotations such as `List[...]`, without adding the required `from typing import List` import. We note that benchmark evaluation inherently involves noise from the stochastic generation. To quantify this variance, we re-ran a subset of benchmarks with multiple random seeds and secret keys. The observed differences between watermarked and non-watermarked conditions fall within the variance introduced by seed/key changes, confirming that watermarking does not systematically degrade or improve performance (see subsection E.1).

4.4 Human Evaluation of Imperceptibility

We assess whether the watermark introduces perceptible quality degradation through a human A/B preference study. Following the methodology of Dathathri et al. (2024), we generate paired responses to questions from ELI5 (Fan et al., 2019) (2,000 English samples) and CaLMQA (Arora et al., 2025) (1,000 each for Arabic, Chinese, Hindi, Japanese), totaling 6,000 question-answer pairs.

Each pair is evaluated by three annotators (via Appen) with qualifications requiring post-graduate education, native-level language fluency, and at least two years of experience. Annotators select among four options: *A is preferred*, *B is preferred*, *both equally good*, or *both equally bad*, without knowing which output is watermarked. We aggregate via majority vote, merging the two tie categories and defaulting split votes (one vote per category) to tie.

²The temperature controls the strength of the watermark since an increased temperature leads to higher entropy.

Results. Table 2 reports preference rates after majority vote aggregation. We test whether the watermark win rate among decisive (non-tie) samples differs from 50% using a two-sided binomial test. No individual language reaches significance (all $p > 0.05$), and no test is significant after Bonferroni correction for the six comparisons ($\alpha/6 = 0.008$). The majority of samples (79%) result in ties, and inter-annotator agreement is high (92% of samples have at least 2/3 consensus on the 4-class scale). We also report the *net win rate*, defined as $(n_{\text{WM}} - n_{\text{Base}})/N$ over all samples including ties: the overall net win rate is +1.35%, indicating a negligible advantage for watermarked outputs.

To rigorously establish imperceptibility rather than merely failing to detect a difference, we apply the Two One-Sided Tests (TOST) procedure (Schuirmann, 1987) for equivalence testing. We test $|P(\text{WM preferred}) - P(\text{Base preferred})| < \Delta$ over all N samples (including ties in the denominator), which provides greater statistical power than restricting to decisive samples alone. With a smallest effect size of interest $\Delta = 5\%$, equivalence is established for all five languages and overall ($p < 0.05$ for all; overall 90% CI: $[-5\%, +5\%]$). Full breakdowns and the equivalence testing methodology are provided in Appendix E.3.

4.5 Localization in Mixed Documents

In practice, watermarked text often forms only a fraction of a document (e.g., AI-generated paragraphs within a human-written report). A global detector scoring the entire text faces two primary challenges: *dilution*, where unwatermarked tokens degrade the signal-to-noise ratio, and *fragmentation*, where watermarked content is scattered across non-contiguous regions. We evaluate TextSeal’s adaptive ensemble (Section 3.3) against global detection by embedding 400-token watermarked answers ($T = 1.0$, top- $p = 0.95$, chosen to increase the watermark signal) into unwatermarked Wikipedia texts. Under **dilution** ($K=1$), we place a single contiguous 400-token block inside documents of increasing length, up to 12,000 tokens (watermarked fraction: 3.3%). Under **fragmentation** ($K>1$), we split the 400 tokens into $K \in \{1, 2, 3, 5\}$ equal fragments interleaved within a fixed 8,000-token document.

Results. As shown in Figure 3 (left), global detection suffers heavily from dilution, degrading at roughly $O(1/T)$ and failing to reach significance ($p=0.01$) beyond $T=4000$. TextSeal’s adaptive ensemble, however, efficiently isolates the signal, maintaining strong detectability ($-\log_{10} p > 4$) even at $T=12,000$ (a $30\times$ dilution). For fragmentation (Figure 3, right), global detectors exhibit flat performance, as they are blind to spatial arrangement. Conversely, the ensemble successfully detects

Figure 3 Localized detection in mixed documents containing 400 watermarked tokens. **(Left) Dilution:** A single watermarked block ($K=1$) embedded in documents of increasing length. Global detection (light blue and red curves) degrades rapidly as the watermarked fraction shrinks, dropping below the $p=0.01$ significance threshold around 4k tokens. The adaptive ensemble (dark blue curve) maintains strong detectability ($-\log_{10} p > 4$) even at 12k tokens (3.3% watermarked). **(Right) Fragmentation:** Watermarked text split into K fragments within an 8000-token document. Global detectors are insensitive to fragmentation (flat curves at $-\log_{10} p \approx 1$), while the ensemble leverages localized search to extract the signal at $K \leq 3$ fragments.

the watermark for up to $K=3$ fragments. Performance only degrades at $K=5$, where individual fragments (~ 80 tokens) become too small to overcome the statistical penalty of multiple-hypothesis testing. Overall, TextSeal’s localized approach dramatically outperforms global baselines whenever watermarked content is reasonably concentrated within the document.

5 Ablations and Analyses

5.1 Diversity Strategies Comparison

We compare four strategies for restoring diversity in Gumbel-max watermarking (full descriptions and proofs in Appendix C): **(1) Stochastic Mixing** mixes the PRF value with a Bernoulli coin (control: mixing rate a); **(2) Periodic Skip** disables watermarking at fixed intervals (control: skip rate α); **(3) Entropy-Normalized Skip** skips watermarking with probability τ uniformly across entropy regimes, preserving distortion-freeness (control: target skip rate τ); **(4) Dual-Key Routing** (subsection 3.1) alternates between two secret keys (control: routing probability $\alpha \in [0, 0.5]$).

Results: Diversity vs. Detectability Trade-off We evaluate Qwen 3.5-27B on 1,000 ELI5 prompts, with reasoning disabled, temperature 1.0, top- $p = 0.95$, maximum generation length 2,048, watermark context size $k = 3$, and two generations per prompt to compute Self-BLEU. For detection, we report both the classical test and the entropy-weighted Gamma test. For each method, we vary the control hyperparameter to trace the Pareto frontier between *diversity* (measured by Self-BLEU, where lower indicates less repetition) and *detectability* (measured by the p -value under $\mathcal{H}_0$; lower means a stronger watermark signal).

Figure 4 illustrates the Pareto frontiers for all five methods. Ideally, a method should push towards the top-left corner (low Self-BLEU, low p -value). Several trends stand out. First, entropy-weighted detection consistently improves every method, often by several orders of magnitude in median p -value, without changing the generation diversity. Second, early-fusion dual-key routing clearly outperforms Fisher-style dual-key aggregation at comparable Self-BLEU, confirming that early fusion is the right detector for routed generation. Third, stochastic mixing is consistently dominated: it reaches similar or worse detectability only at much higher Self-BLEU, making it a poor trade-off in practice.

Among the strongest methods, entropy skip and early-fusion dual-key routing define the best Pareto frontier. Entropy skip is slightly stronger at the highest-detectability end, while early-fusion dual-key routing remains very close across the full sweep and has the practical advantage of mapping directly to speculative decoding and MTP-style deployments. We therefore select dual-key routing as the default diversity mechanism for TextSeal in all experiments.

Figure 4 Pareto frontier of diversity strategies. Self-BLEU is lower-is-better and median $-\log_{10}(p)$ is higher-is-better. Solid lines use the classical detector; dashed lines use entropy weighting. Early-fusion dual-key routing outperforms Fisher at matched diversity, and together with entropy skip defines the strongest frontier.

5.2 False Positive Rate Check

A reliable detector must strictly control its empirical False Positive Rate (FPR) at any nominal threshold τ . We validate this on 1 million unwatermarked Wikipedia passages (256 tokens each), rather than ELI5 answers to have more texts and cover a wider distribution. We plot in Figure 5 the empirical FPR against τ ; perfect calibration aligns with the diagonal, while curves *above* it indicate safe, conservative behavior. Under standard unweighted dual-key detection presented in subsection 3.1 (Figure 5, left), all methods tightly track the diagonal down to $\tau \approx 10^{-4}$. Under lightweight (0.8B) entropy-weighted detection as described in subsection 3.2 (Figure 5, right), TextSeal remains strictly well-calibrated.

5.3 Generalization: Multilingual Question Answering

The experiments above use a single model (Qwen 3.5-72B) on English text. To test whether TextSeal generalizes across models, languages, and scripts, we evaluate on a multilingual question-answering task using a different model: GPT-OSS-20B, OpenAI’s open-weights 20B-parameter reasoning model, with reasoning enabled, on two datasets: ELI5 (English, 2,000 questions) and CalmQA (Arabic, Chinese, Hindi, Japanese; 1,000 questions each), totaling 6,000 paired samples. Each question is answered with and without watermarking (top- $p = 0.95$, temperature= 0.7). Full experimental details are in subsection E.2.

Quality Comparison. Table 3 compares generation quality between watermarked and non-watermarked outputs. Semantic similarity between WM and Non-WM answers is high (SBERT mean 0.86), indicating that watermarking does not meaningfully alter content. Reasoning lengths show a small increase with watermarking ($\sim 16\%$ more reasoning tokens, especially in other languages than English), likely due to sampling variance rather than a systematic effect. Refusal rates are low under both conditions ($< 1\%$). Script consistency is $> 98\%$ for all languages except Japanese (90%), with a small increase of 1% for WM. We use McNemar’s tests (McNemar, 1947) to confirm that there is no statistically significant difference between conditions for either refusal rates ($p = 0.41$) or script consistency ($p = 0.21$); see subsection E.2 for details. TextSeal achieves 63.3% TPR at 0.1% FPR overall; per-language detection curves are in App. E.2.

5.4 Real-World Considerations: Embedding and Detection Efficiency

We evaluate TextSeal’s computational efficiency during both generation and detection to ensure it is lightweight enough for large-scale deployment.

Generation Overhead. Table 4 details the sampling overhead during autoregressive decoding. TextSeal evaluates a fused dual-key pseudorandom function (PRF) restricted strictly to the top- p survivor tokens (~ 200 tokens), avoiding full-vocabulary hashes. This adds only ~ 0.07 ms per token ($\leq 0.3\%$ overhead). In contrast, SynthID’s iterative tournament sampling requires d sequential rounds of top- p

Figure 5 Theoretical FPR (τ) vs. empirical FPR under standard detection (left) and entropy-weighted linear detection (right), on 1M unwatermarked Wikipedia texts (256 tokens each) The dashed diagonal indicates perfect calibration. All curves lie above the diagonal (conservative): the empirical FPR never exceeds the nominal level. Line styles distinguish parameter settings within each method.

Table 3 Quality comparison between watermarked (WM) and non-watermarked (Non-WM) answers on 6,000 multilingual QA pairs. SBERT: cosine similarity between WM and Non-WM answers (all-MiniLM-L6-v2). Reasoning/Answer tokens: average per response. Refusal/Script: percentage of responses with refusal or wrong language script. Results show no meaningful quality difference between conditions.

Language	SBERT	Reasoning tokens		Answer tokens		Refusal %		Wrong Script %	
		WM	Non-WM	WM	Non-WM	WM	Non-WM	WM	Non-WM
English	0.870	168	149	124	121	0.8	0.7	0.0	0.0
Arabic	0.914	296	232	161	155	0.6	0.6	0.6	0.6
Chinese	0.815	224	203	144	146	0.6	0.3	0.7	0.6
Hindi	0.920	293	229	166	161	1.1	1.1	1.1	1.1
Japanese	0.761	294	280	181	181	0.6	0.2	9.0	7.8
Overall	0.858	240	207	150	147	0.7	0.6	1.9	1.7

Table 4 Per-token sampling overhead of TextSeal and SynthID watermarking on a single H200 GPU. Each method is measured on the *same* logits, isolating the sampling cost. TextSeal uses dual-key Gumbel-Max ($\alpha=0.1$, n -gram=3); SynthID uses tournament depth $d=10$. Median over 30 prompts of ELI-5 $\times$ 400 tokens.

Model	Fwd (ms)	No Watermark			TextSeal		SynthID	
		Sample (ms)	tok/s		Sample (ms)	Overhead	Sample (ms)	Overhead
Qwen 3.5-0.8B	21.4	0.37	45.9		0.43	0.3%	0.61	1.1%
Qwen 3.5-2B	21.5	0.36	45.8		0.43	0.3%	0.60	1.1%
Qwen 3.5-4B	30.3	0.38	32.6		0.44	0.2%	0.62	0.8%
Qwen 3.5-9B	31.3	0.38	31.5		0.45	0.2%	0.62	0.8%
Qwen 3.5-27B	61.9	0.39	16.1		0.46	0.1%	0.63	0.4%

reweightings and a multinomial sampling step, costing ~ 0.6 ms per token (0.4–1.1% overhead). Crucially, both methods operate entirely on the logits, requiring no model parameter changes or KV-cache modifications, ensuring immediate compatibility with standard serving infrastructure.

Detection Efficiency and Proxy Scaling. For detection, we evaluate the optimal proxy model size for entropy weighting (Section 3.2) across varying attack strengths (Figure 6). Standard unweighted detection is highly efficient (0.007 ms/token, 0 GB VRAM overhead) but yields a baseline median $-\log_{10} p$ of 4.8. Entropy weighting with the full 27B model significantly boosts this score to 8.2, but incurs massive overhead (50.1 GB VRAM, 0.213 ms/token). However, the 4-bit quantized 0.8B model

Figure 6 Entropy-aware detection performance and computational costs. **(Left)** Detectability under varying attack strengths. The highly efficient 4-bit 0.8B model boosts base detectability by ~ 1.3 orders of magnitude, capturing much of the theoretical maximum boost (+3.4) provided by the 27B generation model. **(Middle)** Detection time per token (log scale). **(Right)** Peak GPU memory allocation (log scale). The 4-bit 0.8B model offers an excellent trade-off, recovering most of the watermark signal while requiring 35 $\times$ less memory.

emerges as the optimal practical choice: it achieves near-parity detectability (6.2) and scales identically against robust attacks, while requiring only 1.4 GB VRAM and 0.115 ms/token.

MTP Speculative Decoding. Multi-token prediction (MTP) speculative decoding accelerates inference via lightweight draft heads that propose multiple tokens in parallel (Gloeckle et al., 2024). TextSeal natively supports this by assigning key A to draft-accepted tokens and key B to target-resampled tokens. Consequently, the mixing parameter α dynamically matches the empirical acceptance rate. We evaluate Qwen 3.5 (2B, 9B, 27B) generating 400-token ELI5 answers under three conditions: standard MTP, MTP with TextSeal, and autoregressive TextSeal. As shown in Figure 7, MTP draft acceptance rates remain identical (29–46%) with and without TextSeal, confirming the dual-key approach is perfectly distortion-free and preserves all speculative efficiency gains. While MTP TextSeal’s detection signal is slightly lower than standard TextSeal due to key mixing dilution ($\alpha < 1$), entropy weighting easily recovers strong significance well above the $p=0.01$ threshold. Perplexity remains identical across all conditions and model sizes, confirming that the dual-key watermark introduces no quality degradation.

6 Watermark Radioactivity: Detecting Distillation via Learnability

A watermark is *radioactive* (Sander et al., 2024) if, when a model is trained on watermarked data, it inherits a detectable token bias. This enables a powerful application beyond text provenance: detecting whether a competitor has distilled your model’s outputs into their own.

Setup. We distill DeepSeek-R1-Distill-Qwen-14B (Guo et al., 2025) (teacher) into Qwen2.5-3B (Team, 2024) (student) on 5,000 curated problems from OpenR1-Math-220k (Hugging Face, 2025). The teacher generates reasoning traces under four watermark schemes: Gumbel-Max (Aaronson and Kirchner, 2023), TextSeal ($\alpha=0.1$), SynthID depth 10 (Dathathri et al., 2024), and an unwatermarked control (all with watermark windows of size 3). Following Muennighoff et al. (2025), we retain traces only if they close their `</think>` block, contain a `\boxed{}` answer (when required), match the reference solution under `math_verify`, and have no 100-character span recurring ≥ 3 times. We also remove problems that the base student already solves correctly, so the distillation set only includes traces that teach the student something new. We then apply LoRA fine-tuning on the remaining traces.

Detection methodology. To test whether the watermark transferred, we use the open-model radioactivity test (Sander et al., 2024). We feed each training trace into the student using *teacher forcing* (providing the ground-truth prefix at each position) and record the student’s top-1 prediction. If the student internalized the watermark bias during training, its predictions should be skewed toward high-PRF tokens. We score each prediction with the watermark PRF and aggregate into a p -value. To get a statistically valid test, we deduplicate at two levels. *Within each trace*, each watermark context

Figure 7 MTP speculative decoding with TextSeal watermarking across Qwen 3.5 model sizes (2B, 9B, 27B) at temperature 0.8, top- p 0.9. *Left:* Draft acceptance rate is unchanged by dual-key watermarking, confirming zero overhead. *Center:* Both TextSeal and MTP TextSeal are well above the $p=0.01$ detection threshold; solid bars show entropy-weighted detection, hatched bars show standard detection. The modest gap between TextSeal and MTP TextSeal is explained by the key-mixing parameter $\alpha < 1$. *Right:* Perplexity is identical across all conditions, confirming that watermarking is distortion-free.

Table 5 Teacher trace quality and detectability. The teacher generates 5,000 traces per method; pass rate is the fraction retained by the four-stage quality filter. Teacher $-\log_{10}(p)$ reports the mean watermark detection power across individual teacher traces. Accuracy is measured on GSM8K (1,319 problems, greedy decoding); the baseline is the pre-training Qwen2.5-3B. [†]TextSeal uses entropy-weighted scoring.

Method	Retained Traces	Pass Rate	Teacher $-\log_{10}(p)$	GSM8K Acc	Δ vs Base
Base Model (Qwen2.5-3B)	—	—	—	64.5%	—
Gumbel-Max	1,991	39.8%	14.89	78.8%	+14.3
TextSeal	2,352	47.0%	33.15 [†]	79.9%	+15.4
SynthID	2,408	48.2%	14.39	75.2%	+10.7
Control	2,400	48.0%	0.39	75.5%	+11.0

window $\mathbf{w}_t$ is scored at most once: if the same k -gram appears more than once in a trace, we score the student’s prediction only at the first occurrence. This is needed to avoid spurious signal: a high-PRF token already inside the input context can be copied by the student through attention rather than retrieved from internalized watermark bias. *Across traces*, we further deduplicate (*context window, predicted token*) tuples globally so that repeated tuples are counted only once. The PRF is deterministic in $(v, \mathbf{w}, K)$, so duplicated tuples produce identical scores and would violate independence in the statistical test. After deduplication, this yields ~ 1.4 – 2.2 M unique scored tokens per method (full setup in subsection E.4).

Results. Figure 8 shows that all three watermarks reliably transfer through distillation, with detection power far exceeding the significance threshold. Under the original setup (each method uses all its retained traces), TextSeal achieves the strongest signal thanks to higher data volume. Once data volume is equalized (controlled conditions in Figure 8b,c), Gumbel-Max dominates, confirming a stronger per-token signal via deterministic argmax; TextSeal achieves comparable overall detectability by retaining more training data. All distilled students substantially improve over the base model (+10–15% on GSM8K), and distilling on watermarked traces does not lead to significant changes compared to the unwatermarked control.

Controlled comparisons. To rule out training data volume as a confound, we repeat the experiment under two controlled conditions: (i) *equal traces*, where each method uses exactly 1,991 traces (the Gumbel-Max minimum, randomly subsampled for the other methods); and (ii) *equal tokens*, where each method is allocated ~ 15.1 M characters. Under equal traces, TextSeal achieves the highest student accuracy (81.0%), followed by SynthID and Control (78.8% each) and Gumbel-Max (77.7%). Under equal tokens, the spread narrows (79.7%/78.6%/79.6%/77.6% for TextSeal/Gumbel-Max/SynthID/Control). Detection remains strong under both controls, validating that the conclusions of Figure 8 are not artifacts of unequal training data volume.

Figure 8 Watermark radioactivity through distillation. Detection power ($-\log_{10}(p)$) vs. number of unique scored tokens under three conditions: original traces, equal-trace control (1,991 each), and equal-token control (~ 15.1 M chars each). TextSeal achieves the strongest signal under the original setup thanks to retaining more traces, while Gumbel-Max dominates under controlled conditions, confirming its stronger per-token signal.

Entropy weighting ablation. For TextSeal we use $\sqrt{\hat{H}}$ entropy-aware scoring by default (subsection 3.2). Figure 9 compares eight weighting functions in the same teacher-forcing setup, spanning normalized-entropy transforms (Sqrt, Log, Linear, Tanh of $\hat{H}_i$) and raw entropy power functions (H_i^β for $\beta \in \{0.5, 1.0, 1.5\}$). The concave $\sqrt{\hat{H}}$ weighting achieves the strongest detection ($p = 3.7 \times 10^{-110}$), improving over the uniform baseline ($p = 2.1 \times 10^{-84}$) by more than 25 orders of magnitude. Concave functions outperform linear and superlinear alternatives because they moderately upweight high-entropy positions—where the watermark has more room to influence token selection (Proposition 3)—without over-amplifying noisy extreme-entropy tokens.

The full benchmark accuracy numbers and further details are given in subsection E.4.

7 Conclusion

We introduced TextSeal, a distortion-free watermark for LLMs that achieves state-of-the-art detectability through dual-key generation, entropy-weighted detection, and localized multi-region search. TextSeal strictly dominates SynthID on the diversity-detectability frontier, preserves model performance across 12 benchmarks, supports speculative decoding and MTP, and transfers through distillation for radioactive tracing.

Limitations. Like all distortion-free sampling watermarks, TextSeal trades diversity—not quality—for detectability. While this trade-off is invisible to users who observe a single generation, it may affect workflows that rely on diverse outputs (best-of- N reranking, creative brainstorming). In practice, modern reasoning models trained with RL already exhibit collapsed entropy, limiting the marginal diversity loss; quantifying this across model families remains open.

Figure 9 Entropy-aware scoring for watermark learnability detection. Detection power ($-\log_{10}(p)$) vs. number of unique scored tokens in the teacher-forcing radioactivity test for TextSeal ($\alpha=0.1$), comparing different entropy weighting functions $w_i^{\text{ent}} = f(H_i)$ against a uniform (unweighted) baseline. The concave $\sqrt{\hat{H}}$ weighting achieves the strongest signal ($p = 3.7 \times 10^{-110}$), improving over the uniform baseline ($p = 2.1 \times 10^{-84}$) by more than 25 orders of magnitude.

Appendix

A More Technical Details on the Methods

A.1 Hash Function Implementation

The PRF takes as input the candidate token x , a context window $\mathbf{w} = (w_1, \dots, w_k)$ of k token IDs, and the secret key K (all of them are integers), and outputs a random integer in $[0, M)$.

We compute the hash as follows:

$$h'(x, \mathbf{w}, K) = \left(p_2 \cdot x + \sum_{i=1}^k w_i \cdot q_i + p_3 \cdot K \right) \cdot p_4, \quad (8)$$

$$h(x, \mathbf{w}, K) = \text{XORShift}(h'(x, \mathbf{w}, K)) \bmod M, \quad (9)$$

where $q_1, \dots, q_k$ are distinct large primes (to ensure that different orderings of the same tokens produce different values), and p_2, p_3, p_4 are additional primes. The first result h' undergoes XOR-shift for better bit dispersion: $h = (h' \cdot p_{\text{mix}}) \oplus ((h' \cdot p_{\text{mix}}) \gg s)$, where p_{mix} is a mixing prime and s is a shift constant.

Finally, we normalize to obtain the uniform pseudo-random value:

$$u = \frac{h(x, \mathbf{w}, K)}{M} \in [0, 1]$$

A.2 Details on SynthID-Text Evaluation

In our experiments, we evaluate *SynthID-Text* (Dathathri et al., 2024) as the state-of-the-art generation-time, distortion free and non deterministic watermark. While traditional methods (such as Gumbel-Max or Soft Red List) apply a single, global shift to the logit distribution, SynthID-Text embeds its signal through a multi-layered *Tournament sampling* mechanism.

Tournament Generation. At each generation step t , the method seeds a pseudo-random function using the preceding k tokens (the context window). Using this seed, the vocabulary $\mathcal{V}$ is pseudo-randomly partitioned into a tournament structure with m layers. At each layer $l \in \{1, \dots, m\}$, a pseudo-random g -value $g_{t,l}$ is computed. Instead of a single binary split, SynthID-Text iteratively reshapes the target LLM’s probability distribution across these m layers. Tokens that consistently win their tournament matches (i.e., those assigned high g -values across multiple layers) see their sampling probabilities exponentially increased. By distributing the watermark across multiple layers, SynthID-Text preserves text quality while embedding a robust signal. In our implementation, we follow the authors’ specification for a binary random function (Bernoulli g -value distribution) to construct this tournament.

Why we avoid SynthID’s Bayesian detector. The original SynthID-Text framework proposes a Bayesian neural network (logistic regression or MLP) trained on a representative dataset to estimate posterior probabilities $P(w|g)$. We avoid this approach for several reasons.

(i) *No false-positive-rate guarantee.* A Bayesian posterior score has no frequentist calibration: there is no principled way to set a decision threshold that guarantees, for example, at most one false accusation in 10^4 documents. This is essential for any legal or regulatory use of watermark detection, where a false positive can constitute a wrongful accusation of AI generation.

(ii) *Distribution dependence.* The trained classifier learns the joint distribution of token scores and watermark presence from its training corpus. Deploying on a different model, domain, language, or decoding strategy invalidates these learned posteriors; in practice, we observed that the Bayesian detector degrades sharply on out-of-domain text, requiring retraining for every new deployment setting.

(iii) *Incompatibility with multiple-testing correction.* Localized detection (subsection 3.3) requires evaluating thousands of candidate windows and applying Bonferroni correction to control the family-wise

error rate. This demands a well-calibrated null distribution for each window, which a learned classifier cannot provide. The Bayesian scores are not p -values and cannot be combined or corrected in a statistically valid manner.

(iv) *Opacity and reproducibility.* A learned classifier is a black box whose decision boundary cannot be formally audited. For provenance claims that may carry legal weight, a closed-form statistical test with an analytically derived null distribution is far more defensible. Moreover, the Bayesian detector is not open-sourced, and despite following the specification in the original supplementary material, we were unable to reproduce comparable results, making fair comparison infeasible.

Our frequentist alternative. To ensure a fair, threshold-independent comparison, we implement a mathematically rigorous frequentist detection pipeline. At detection time, for a given token x_t and its context, we reconstruct the PRF-seeded tournament and extract the sequence of m layer-wise g -values $g_{t,1}, \dots, g_{t,m}$. Because earlier layers in the tournament contribute more watermarking evidence than later layers, we compute a *Weighted Mean Score* for the token:

$$s_t = \sum_{l=1}^m \alpha_l g_{t,l} \quad (10)$$

where $\alpha_1 \geq \dots \geq \alpha_m \geq 0$ are linearly decaying weights. Over a sequence of N valid tokens, we sum the scores to obtain a test statistic $S = \sum_{t=1}^N s_t$. Under the null hypothesis $\mathcal{H}_0$ (unwatermarked text), the g -values follow the unwatermarked uniform or Bernoulli distribution. We analytically compute the mean μ_0 and variance σ_0^2 of the weighted sum under $\mathcal{H}_0$. We then compute a final Z-score for the sequence:

$$Z_{\text{SynthID}} = \frac{S - N\mu_0}{\sigma_0\sqrt{N}} \quad (11)$$

The significance is given by the standard normal survival function $p = 1 - \Phi(Z_{\text{SynthID}})$.

A.3 Other Watermark Schemes

We describe below the other watermarking schemes referenced in this work.

Green-list/Red-list. Kirchenbauer et al. (2023a) modify the logit vector based on the watermark context window and secret key K . A token v is classified as “green” if $\text{PRF}(v, \mathbf{w}, K) < \gamma$ (typically $\gamma=0.5$), and its logit is incremented by δ : $\tilde{\ell}_v = \ell_v + \delta$ for green tokens, $\tilde{\ell}_v = \ell_v$ otherwise. Detection counts green tokens and performs a binomial test. This method is *not* distortion-free: the additive bias alters every generation.

MorphMark. Wang et al. (2025) adaptively adjust watermark strength based on context. Let $P_G = \sum_{v \in \text{GreenList}} p_v$ be the total probability mass on green tokens. If $P_G \leq p_0$ (a threshold), no watermark is applied; otherwise, probabilities are rescaled with an adaptive boost factor $r = \min(\kappa P_G, 1)$. This reduces distortion compared to vanilla green-red but is still *not* distortion-free.

DiPMark. Wu et al. (2023) introduce a distortion-free variant of green-red watermarks using a pseudorandom permutation π (seeded by context and K) to reorder tokens before applying a bias. The bias preserves the original distribution in expectation over the randomness of π .

WaterMax. Giboulot and Furon (2024) generate several candidate chunks from the original LLM distribution and select outputs with the highest watermark score. This is distortion-free by construction but requires multiple generations per query, making it impractical for production.

A.4 Radioactivity Test Protocol

We detail the radioactivity test methodology from Sander et al. (2024, 2025).

Teacher-forcing setup. We feed the watermarked training traces into the suspect (student) model using teacher forcing: at each position t , the model receives the ground-truth prefix $x_{<t}$ from the watermarked trace and produces a prediction. Let $\hat{x}_t = \arg \max_{v \in \mathcal{V}} P_\theta(v \mid x_{<t})$ denote the student’s top-1 prediction at step t . The key insight is that teacher forcing isolates the model’s learned token preferences from confounding factors like sampling noise, requiring only a single forward pass over existing traces rather than expensive autoregressive generation.

Test statistic. We score each prediction using the watermark’s PRF: $R_t = \text{PRF}(\hat{x}_t, \mathbf{w}_t, K)$, where $\mathbf{w}_t$ is the context window of teacher tokens preceding position t . If the student internalized the watermark bias during training, its top-1 predictions will be systematically skewed toward high-PRF tokens, producing a significant test statistic.

Deduplication. We deduplicate at two levels, each for a different reason: (i) *within each trace*, each context window $\mathbf{w}_t$ is scored only once. This is necessary because the teacher’s watermarked tokens appear in the student’s input context during teacher forcing: if an n -gram that was biased toward high-PRF values appears multiple times, the student might simply copy it from context rather than predicting it from internalized preferences, creating a false signal (Sander et al., 2024); (ii) *across traces*, all (context window, predicted token) pairs are pooled and deduplicated, because the PRF is deterministic and shared (context, token) tuples across different training examples would yield identical scores, violating independence (Fernandez et al., 2023). After deduplication, under $\mathcal{H}_0$ (the student is unaware of K), the scores are independent and follow their null distribution, enabling exact p -value computation.

B Gumbel-max proofs

The following results were presented by Aaronson and Kirchner (2023) and formalized by Fernandez et al. (2023). Some elements of these proofs are used later, so we restate them here. An overview of the Gumbel-max generation scheme is presented in Figure 10.

Figure 10 Standard Gumbel-Max watermarking (see section 2). The LLM uses all previous tokens to predict probabilities, while the PRF uses only the last k tokens (watermark context $\mathbf{w}$) to generate pseudo-random values R_v for each candidate token v . The token maximizing R_v^{1/p_v} is selected.

Proposition 4 (Sampling probability, restated from [Proposition 1](#)). *Consider a discrete distribution $\mathbf{p} = (p_1, \dots, p_V)$ and $V = |\mathcal{V}|$ random variables $\mathbf{R} = (R_1, \dots, R_V)$ s.t. $R_v \stackrel{iid}{\sim} \mathcal{U}_{[0,1]}$. Let $V^* = \arg \max_v R_v^{1/p_v}$. Then: $\mathbb{P}(V^* = v) = p_v$.*

Proof of Proposition 1. For any $v \in \mathcal{V}$, $R_v \stackrel{iid}{\sim} \mathcal{U}_{[0,1]}$ so, $-\ln(R_v)$ follows an [exponential distribution](#) $\mathcal{E}(1)$. Let $Z_v := -\frac{1}{p_v} \ln(R_v)$. By construction, $Z_v \sim \mathcal{E}(p_v)$, with density $f_{Z_v}(z) = p_v e^{-p_v z}$. We now have:

$$V^* = \arg \max_v R_v^{1/p_v} = \arg \min_v Z_v. \quad (12)$$

A well known result about exponential laws is that:

$$\underline{Z} = \min_v Z_v \sim \mathcal{E}\left(\sum_v p_v\right) = \mathcal{E}(1), \quad (13)$$

$$\mathbb{P}(V^* = v) = \frac{p_v}{\sum_j p_j} = p_v. \quad (14)$$

This shows that for a given secret vector $\mathbf{r}$, the watermarking chooses a word which may be unlikely (low probability p_{V^*}). Yet, on expectation over the secret keys, i.e., over r.v. $\mathbf{R} = (R_1, \dots, R_V)$, the distribution of the chosen token follows the distribution given by the LLM. $\square$

Corollary 2 (Restated from [Corollary 1](#)). *Conditionally on $V^* = v$, $R_{V^*} \sim \text{Beta}(1/p_v, 1)$.*

Proof of Corollary 1. From the proof above, $\underline{Z} = \min_v Z_v \sim \mathcal{E}(1)$ and $V^* = \arg \min_v Z_v$. A standard property of competing exponentials is that the identity of the winner is independent of the winning time: $V^* \perp \underline{Z}$. Conditioning on $V^* = v$, we therefore still have $\underline{Z} \sim \mathcal{E}(1)$, and:

$$\underline{Z} = Z_v = -\frac{1}{p_v} \ln(R_v) \sim \mathcal{E}(1), \quad (15)$$

which gives $R_v = e^{-p_v E}$ with $E \sim \mathcal{E}(1)$, with p.d.f. $f_{R_v}(r) = \frac{r^{1/p_v-1}}{p_v}$. Therefore, $R_v \mid V^* = v \sim \text{Beta}(1/p_v, 1)$. $\square$

Proposition 5 (Expected score under $\mathcal{H}_1$, restated from [Proposition 3](#)). *Under $\mathcal{H}_1$ (text is watermarked), $\mathbb{E}(S_T) \geq T + \left(\frac{\pi^2}{6} - 1\right) H_T$, where $H_T = -\sum_{t=1}^T p_t \ln(p_t)$ is the entropy of the completion.*

Proof of Proposition 3. From the corollary above, $R_t = \exp(-p_t E)$ with $E \sim \mathcal{E}(1)$, so:

$$\begin{aligned} \mathbb{E}(S) &= -\mathbb{E}\left[\sum_{t=1}^T \ln(1 - \exp(-p_t E))\right] \\ &= -\sum_{t=1}^T \int_0^\infty \ln(1 - e^{-p_t x}) e^{-x} dx \\ &= -\sum_{t=1}^T \int_0^1 \frac{1}{p_t} r^{1/p_t-1} (-\ln(1-r)) dr \\ &\quad (\text{by change of variable } x = -1/p_t \ln(r)) \end{aligned}$$

Then, using integration by parts with $u = 1 - r^{1/p_t}$ and $v = \ln(1-r)$, the integral becomes:

$$-\int_0^1 \frac{1}{p_t} r^{1/p_t-1} \ln(1-r) dr = \int_0^1 \frac{1 - r^{1/p_t}}{1-r} dr = \mathcal{H}_{1/p_t}$$

where $\mathcal{H}_z$ is the z -th [harmonic number](#) also defined as $\mathcal{H}_z = \sum_{n=1}^{\infty} \frac{1}{n} - \frac{1}{n+z}$. Therefore, we have:

$$\begin{aligned} - \int_0^1 \frac{1}{p_t} r^{1/p_t-1} \ln(1-r) dr &= \sum_{n=1}^{\infty} \frac{1}{n} - \frac{1}{n+1/p_t} \\ &= 1 + \sum_{n=1}^{\infty} \frac{1}{n+1} - \frac{1}{n+1/p_t}. \end{aligned}$$

Now, $\forall n \in \mathbb{N}^*$, we have:

$$\begin{aligned} (n+1)^2 \left(\frac{1}{n+1} - \frac{1}{n+1/p_t} \right) &= \frac{(n+1)(n+1/p_t) - (n+1)^2}{n+1/p_t} \\ &= \frac{1+n}{1/p_t+n} (1/p_t - 1) \\ &\geq -\frac{1+n}{1/p_t+n} \ln(p_t) \\ &\geq -p_t \ln(p_t). \end{aligned}$$

Therefore, by summing over all $t \in [1, T]$,

$$\begin{aligned} \mathbb{E}(S) &\geq T + \left(\sum_{n=1}^{\infty} \frac{1}{(n+1)^2} \right) \left(\sum_{t=1}^T -p_t \ln(p_t) \right) \\ &= T + \left(\frac{\pi^2}{6} - 1 \right) H_T. \end{aligned}$$

□

C Proofs on Diversity Schemes for Gumbel Max

We derive bounds on the expected detection score $\mathbb{E}[S_T]$ under $\mathcal{H}_1$ for each diversity strategy described in [subsection 5.1](#) and illustrated in [Figure 11](#). All bounds decompose as the standard Gumbel bound ([Proposition 3](#)) plus a correction term capturing the cost of the diversity mechanism.

Recall that under the standard Gumbel scheme, $R_t \sim \text{Beta}(1/p_t, 1)$ and the expected per-token score is $\mathbb{E}[s_t] = \mathcal{H}_{1/p_t}$, leading to $\mathbb{E}[S_T] \geq T + (\frac{\pi^2}{6} - 1)H_T$. In each case below, some tokens are either unwatermarked or have a modified distribution of R_t . For unwatermarked tokens, $R_t \sim \mathcal{U}[0, 1]$ and $\mathbb{E}[s_t] = 1$.

C.1 Dual-Key Routing

Dual-key routing ([subsection 3.1](#)) maintains two secret keys $k^{(1)}$ and $k^{(2)}$. At each generation step, key $k^{(1)}$ is selected with probability $1 - \alpha$ and $k^{(2)}$ with probability α . The token is produced via Gumbel-

Figure 11 Overview of diversity mechanisms for Gumbel-Max watermarking. Each column shows how the token x_t is generated. All methods except Adaptive Skip preserve the distortion-free property. The key distinction lies in *where* randomness is injected: in the PRF value (Mixing), in the decision to watermark (Skip variants, Warmup), or in the key selection (Dual-Key Routing).

Max using the selected key. Detection aggregates scores from both keys: $s_i = (1 - \alpha) \cdot s_i^{(1)} + \alpha \cdot s_i^{(2)}$.

Proposition 6 (Bound on expected score under dual-key routing, single-key detection). *Under dual-key routing with parameter $\alpha \in [0, 1]$ (key $k^{(1)}$ selected with probability $1 - \alpha$, key $k^{(2)}$ with probability α), detection using a single key $k^{(1)}$ yields:*

$$\mathbb{E}[S_T^{(1)}] \geq T + (1 - \alpha) \left(\frac{\pi^2}{6} - 1 \right) H_T \quad (16)$$

Proof. At each step t , key $k^{(1)}$ is selected with probability $1 - \alpha$ and key $k^{(2)}$ with probability α . For detection using key $k^{(1)}$:

- With probability $1 - \alpha$: the PRF value $R_t^{(1)}$ is the one used for generation, so $R_t^{(1)} \sim \text{Beta}(1/p_t, 1)$ and $\mathbb{E}[s_t^{(1)}] = \mathcal{H}_{1/p_t}$.
- With probability α : the token was generated using key $k^{(2)}$, so $R_t^{(1)}$ is independent of the generation process. It is effectively uniform and $\mathbb{E}[s_t^{(1)}] = 1$.

Summing over T tokens:

$$\mathbb{E}[S_T^{(1)}] = (1 - \alpha) \sum_{t=1}^T \mathcal{H}_{1/p_t} + \alpha T$$

Applying the standard bound (Proposition 3) to $\sum_t \mathcal{H}_{1/p_t} \geq T + (\frac{\pi^2}{6} - 1)H_T$:

$$\mathbb{E}[S_T^{(1)}] \geq (1 - \alpha) \left[T + \left(\frac{\pi^2}{6} - 1 \right) H_T \right] + \alpha T = T + (1 - \alpha) \left(\frac{\pi^2}{6} - 1 \right) H_T$$

□

This bound matches the random skip bound (Proposition 10) with α playing the role of the skip rate: from the perspective of a single-key detector, tokens generated with the other key look exactly like skipped tokens. The advantage of dual-key routing is that the aggregated score (Equation 3) lets every token contribute signal from at least one key, as formalized below.

Proposition 7 (Expected score under dual-key Early Fusion detection). *Under dual-key routing with parameter $\alpha \in [0, 1]$, detecting with the aggregated score $s_i = (1 - \alpha) \cdot s_i^{(1)} + \alpha \cdot s_i^{(2)}$ yields:*

$$\mathbb{E}[S_T] \geq T + (\alpha^2 + (1 - \alpha)^2) \left(\frac{\pi^2}{6} - 1 \right) H_T \quad (17)$$

Proof. At each step t , key $k^{(1)}$ is active with probability $1 - \alpha$ and key $k^{(2)}$ with probability α . The aggregated per-token score is $T_t = (1 - \alpha)s_t^{(1)} + \alpha s_t^{(2)}$.

- If $k^{(1)}$ was used (prob. $1 - \alpha$): $s_t^{(1)}$ has the watermarked distribution ($\mathbb{E}[s_t^{(1)}] = \mathcal{H}_{1/p_t}$) and $s_t^{(2)}$ is uniform ($\mathbb{E}[s_t^{(2)}] = 1$), giving $\mathbb{E}[T_t] = (1 - \alpha)\mathcal{H}_{1/p_t} + \alpha$.
- If $k^{(2)}$ was used (prob. α): $s_t^{(1)}$ is uniform ($\mathbb{E}[s_t^{(1)}] = 1$) and $s_t^{(2)}$ has the watermarked distribution ($\mathbb{E}[s_t^{(2)}] = \mathcal{H}_{1/p_t}$), giving $\mathbb{E}[T_t] = (1 - \alpha) + \alpha\mathcal{H}_{1/p_t}$.

Taking expectation over the key choice:

$$\begin{aligned} \mathbb{E}[T_t] &= (1 - \alpha)[(1 - \alpha)\mathcal{H}_{1/p_t} + \alpha] + \alpha[(1 - \alpha) + \alpha\mathcal{H}_{1/p_t}] \\ &= [(1 - \alpha)^2 + \alpha^2]\mathcal{H}_{1/p_t} + 2\alpha(1 - \alpha) \\ &= \theta_R \mathcal{H}_{1/p_t} + (1 - \theta_R) \end{aligned}$$

where $\theta_R = \alpha^2 + (1 - \alpha)^2$. Summing over T tokens:

$$\mathbb{E}[S_T] = \theta_R \sum_{t=1}^T \mathcal{H}_{1/p_t} + (1 - \theta_R) T$$

Applying the standard bound $\sum_t \mathcal{H}_{1/p_t} \geq T + (\frac{\pi^2}{6} - 1)H_T$:

$$\mathbb{E}[S_T] \geq \theta_R \left[T + \left(\frac{\pi^2}{6} - 1 \right) H_T \right] + (1 - \theta_R) T = T + \theta_R \left(\frac{\pi^2}{6} - 1 \right) H_T$$

□

Note that $\theta_R = \alpha^2 + (1 - \alpha)^2 \leq 1 - \alpha$ for $\alpha \leq 0.5$, so the expected score under Early Fusion is actually lower than under single-key detection (Proposition 6). The power advantage of Early Fusion comes not from a higher expected score, but from the reduced null variance (θ_R per token instead of 1), which yields a better Z-score as shown below.

C.1.1 Power Analysis: Early vs. Late Fusion

We analyze the statistical power of the Early Fusion test compared to a classical single-key baseline and alternative Late Fusion strategies using the Z-score (Signal-to-Noise Ratio) separation:

$$Z = \frac{\mathbb{E}[S|H_1] - \mathbb{E}[S|H_0]}{\sqrt{\text{Var}(S|H_0)}}$$

Assume a standard Gumbel-Max test where an unwatermarked token yields an expected score of 1 with a variance of 1, and a successfully watermarked token yields an expected score $\mu_w > 1$.

Single-Key Baseline. For a traditional single-key test with n tokens, the expected score sum under H_1 is $n\mu_w$, and under H_0 is n . The null variance is n .

$$Z_{\text{base}} = \frac{n\mu_w - n}{\sqrt{n}} = \sqrt{n}(\mu_w - 1)$$

Early Fusion: Unweighted ($w = 0.5$). For the unweighted test, the expected score per token is $\mathbb{E}[\bar{s}_i] = \frac{\mu_w + 1}{2}$ regardless of which key generated it. The null variance is $\text{Var}(\bar{s}_i) = \frac{1^2 + 1^2}{2^2} = 0.5$.

$$Z_{\text{early}} = \frac{n(\frac{\mu_w + 1}{2}) - n}{\sqrt{0.5n}} = \frac{n(\mu_w - 1)}{2\sqrt{0.5n}} = \frac{\sqrt{n}(\mu_w - 1)}{\sqrt{2}}$$

Thus, $Z_{\text{early}} = \frac{1}{\sqrt{2}} Z_{\text{base}} \approx 0.707 Z_{\text{base}}$. This proves that unweighted Early Fusion is perfectly **invariant to α** , but requires exactly twice as many tokens ($2n$) as the single-key baseline to reach the same statistical confidence.

Early Fusion: Optimal Weighted ($w = \alpha$). If the routing probability α is known (e.g., via speculative decoding acceptance rates) and we use optimal weights $w = \alpha$, the expected token score under H_1 becomes $\mathbb{E}[s_i] = \alpha(\alpha\mu_w + 1 - \alpha) + (1 - \alpha)((1 - \alpha)\mu_w + \alpha)$. Simplifying this and calculating the Z-score yields:

$$Z_\alpha = \sqrt{n}(\mu_w - 1)\sqrt{\alpha^2 + (1 - \alpha)^2}$$

When $\alpha = 0.5$ (maximum diversity), $Z_\alpha = Z_{\text{early}} \approx 0.707 Z_{\text{base}}$. When $\alpha = 0.1$ (typical for draft model acceptance in speculative decoding), $Z_\alpha = \sqrt{0.1^2 + 0.9^2} Z_{\text{base}} \approx 0.905 Z_{\text{base}}$. This demonstrates that the weighted test recovers nearly 30% of the statistical power lost to diversity when the generation rate is skewed.

Superiority over Late Fusion. We can now formally demonstrate why token-level aggregation outperforms independent per-key testing (late fusion). Late fusion evaluates each key's scores independently across the entire sequence ($S^{(1)} = \sum s_i^{(1)}$ and $S^{(2)} = \sum s_i^{(2)}$) and then combines their resulting p-values (e.g., via Fisher's method or by taking the minimum p-value).

Assuming without loss of generality that $\alpha \geq 0.5$, the expected signal for the dominant key over the null is $n\alpha(\mu_w - 1)$. The variance remains n . The statistical power of the combined Late Fusion test is ultimately bounded by the strongest independent signal it receives, which achieves at best:

$$Z_{\text{late}} \approx \frac{n\alpha(\mu_w - 1)}{\sqrt{n}} = \sqrt{n}\alpha(\mu_w - 1) = \alpha Z_{\text{base}}$$

To prove optimal Early Fusion natively dominates Late Fusion, we compare their Z-scores. We must show that $Z_\alpha > Z_{\text{late}}$, which simplifies to proving $\sqrt{\alpha^2 + (1 - \alpha)^2} > \alpha$ for any $\alpha \in (0, 1)$:

$$\alpha^2 + (1 - \alpha)^2 = \alpha^2 + (1 - 2\alpha + \alpha^2) = 2\alpha^2 - 2\alpha + 1$$

We test the inequality $2\alpha^2 - 2\alpha + 1 > \alpha^2$:

$$\alpha^2 - 2\alpha + 1 > 0 \implies (\alpha - 1)^2 > 0$$

Since $(\alpha - 1)^2$ is strictly positive for all $\alpha \in (0, 1)$, it follows that $Z_\alpha > Z_{\text{late}}$. Therefore, token-level aggregation strictly dominates independent per-key testing by preserving the complementary signal distributed across both keys ($k^{(1)}$ and $k^{(2)}$) at the token level, rather than systematically treating the minority key's tokens as noise during independent sequence-level evaluations.

C.2 Stochastic Mixing

Stochastic mixing introduces true randomness by mixing the deterministic PRF value r_1 with a Bernoulli coin. Given a parameter $a \in (0, 1)$, the mixed value is $r = a \cdot r_1$ with probability a , or $r = a + (1 - a) \cdot r_1$ with probability $1 - a$. The mixed r remains uniform (distortion-free), but detection uses only r_1 .

Proposition 8 (Bound on expected score under mixing). *Under stochastic mixing with parameter $a \in (0, 1)$, detection is performed using r_1 (the deterministic PRF value). The expected score satisfies:*

$$\mathbb{E}[S_T] > T + \left(\frac{\pi^2}{6} - 1\right) H_T + \sum_{t=1}^T (1 - a^{1/p_t}) \ln(1 - a) \quad (18)$$

Proof. Let $R \sim \text{Beta}(1/p, 1)$ be the random variable selected during sampling. The score for a single token is $s = -\ln(1 - r_1)$, where r_1 is recovered from R as: $r_1 = R/a$ if $R \in [0, a]$, and $r_1 = (R - a)/(1 - a)$ if $R \in [a, 1]$.

We decompose $\mathbb{E}[s]$ by interval:

$$\mathbb{E}[s] = \underbrace{\int_0^a -\ln(1 - r/a) f_R(r) dr}_{I_1} + \underbrace{\int_a^1 -\ln\left(1 - \frac{r - a}{1 - a}\right) f_R(r) dr}_{I_2}$$

For I_2 : using $1 - \frac{r - a}{1 - a} = \frac{1 - r}{1 - a}$:

$$I_2 = \int_a^1 [-\ln(1 - r) + \ln(1 - a)] f_R(r) dr = \int_a^1 -\ln(1 - r) f_R(r) dr + (1 - a^{1/p}) \ln(1 - a)$$

since $\mathbb{P}(R > a) = 1 - a^{1/p}$.

For I_1 : since $r/a \geq r$ for $r \in [0, a]$, we have $-\ln(1 - r/a) \geq -\ln(1 - r)$, giving $I_1 \geq \int_0^a -\ln(1 - r) f_R(r) dr$.

Summing yields $\mathbb{E}[s] \geq \mathbb{E}[s_{\text{std}}] + (1 - a^{1/p}) \ln(1 - a)$ where $\mathbb{E}[s_{\text{std}}] = \mathcal{H}_{1/p}$. Applying the standard bound and summing over T tokens gives the result. $\square$

Proposition 9 (Distortion-freeness of mixing). *The mixed variable r follows $\mathcal{U}[0, 1]$, so the sampled token follows the model distribution $\mathbf{p}$.*

Proof. Let $F_R(x) = \mathbb{P}(r \leq x)$. For $x \leq a$: $r \leq x$ requires $r_0 = 0$, giving $\mathbb{P}(r \leq x) = a \cdot \mathbb{P}(r_1 \leq x/a) = a \cdot x/a = x$. For $x > a$: $\mathbb{P}(r \leq x) = a + (1 - a) \cdot \frac{x - a}{1 - a} = x$. Since $F_R(x) = x$, we have $r \sim \mathcal{U}[0, 1]$. $\square$

Behavior of the penalty. The penalty $(1 - a^{1/p}) \ln(1 - a)$ is always non-positive (since $\ln(1 - a) < 0$) and vanishes at both extremes: as $a \rightarrow 0$, $\ln(1 - a) \rightarrow 0$; as $a \rightarrow 1$, $(1 - (1 - \epsilon)^{1/p}) \ln(\epsilon) \sim \frac{\epsilon}{p} \ln(\epsilon) \rightarrow 0$. This is expected since in these extremes, all tokens take the same route, which makes it similar to vanilla Gumbel-max.

C.3 Random Skip

Random skip disables the watermark independently at each token with probability α , reverting to standard sampling from $\mathbf{p}$. This blindly injects randomness to break deterministic loops, uniformly attenuating the detection signal.

Proposition 10 (Bound on expected score under periodic skip). *Under periodic skip with rate $\alpha \in [0, 1]$ (each token is independently skipped with probability α), the expected score satisfies:*

$$\mathbb{E}[S_T] \geq T + (1 - \alpha) \left(\frac{\pi^2}{6} - 1 \right) H_T \quad (19)$$

Proof. At each step t , with probability $1 - \alpha$ the watermark is active and $\mathbb{E}[s_t] = \mathcal{H}_{1/p_t}$; with probability α the watermark is skipped and $\mathbb{E}[s_t] = 1$. Summing:

$$\mathbb{E}[S_T] = (1 - \alpha) \sum_{t=1}^T \mathcal{H}_{1/p_t} + \alpha T$$

Applying the standard bound (Proposition 3) to $\sum_t \mathcal{H}_{1/p_t} \geq T + (\frac{\pi^2}{6} - 1) H_T$:

$$\mathbb{E}[S_T] \geq (1 - \alpha) \left[T + \left(\frac{\pi^2}{6} - 1 \right) H_T \right] + \alpha T = T + (1 - \alpha) \left(\frac{\pi^2}{6} - 1 \right) H_T$$

□

The entropy-dependent signal is uniformly attenuated by a factor $(1 - \alpha)$, regardless of the token entropy. This is wasteful compared to adaptive strategies that selectively skip only low-signal tokens.

C.4 Adaptive Skip

Adaptive skip disables the watermark selectively when the model is highly confident. At each step, the token is produced via Gumbel-Max, but if the winning PRF value R_{V^*} falls below a threshold τ , the watermark is discarded and the token is resampled from $\mathbf{p}$. Low R_{V^*} indicates the token won due to high probability mass rather than a favorable PRF draw, so skipping it sacrifices little detection signal.

Proposition 11 (Adaptive skip is not distortion-free). *Under adaptive skip with threshold $\tau \in (0, 1)$, the output distribution is:*

$$\mathbb{P}(\text{output} = v) = p_v \left(1 - \tau^{1/p_v} + \sum_{w \in \mathcal{V}} p_w \tau^{1/p_w} \right) \quad (20)$$

which differs from p_v unless $\mathbf{p}$ is uniform.

Proof. Let V^* be the initial token selected by the Gumbel-max trick, where $\mathbb{P}(V^* = v) = p_v$. By Corollary 1, the conditional distribution of the pseudo-random value R_v is $\text{Beta}(1/p_v, 1)$. The watermark is skipped if $R_{V^*} < \tau$.

The marginal probability of outputting a specific token v decomposes into two disjoint events: keeping the initially selected v , or skipping and resampling $X_t = v$ from the original distribution $\mathbf{p}$:

$$\begin{aligned}
\mathbb{P}(\text{output} = v) &= \mathbb{P}(V^* = v, R_v \geq \tau) + \mathbb{P}(\text{skip})\mathbb{P}(X_t = v) \\
&= \mathbb{P}(V^* = v)\mathbb{P}(R_v \geq \tau \mid V^* = v) + \left(\sum_{w \in \mathcal{V}} \mathbb{P}(V^* = w)\mathbb{P}(R_w < \tau \mid V^* = w) \right) \mathbb{P}(X_t = v) \\
&= p_v \cdot \mathbb{P}(R_v \geq \tau \mid V^* = v) + \left(\sum_{w \in \mathcal{V}} p_w \mathbb{P}(R_w < \tau \mid V^* = w) \right) p_v \\
&= p_v \left(1 - \tau^{1/p_v} \right) + p_v \sum_{w \in \mathcal{V}} p_w \tau^{1/p_w} \\
&= p_v \left(1 - \tau^{1/p_v} + \sum_{w \in \mathcal{V}} p_w \tau^{1/p_w} \right)
\end{aligned}$$

For the mechanism to be distortion-free, we require $\mathbb{P}(\text{output} = v) = p_v$ for all $v \in \mathcal{V}$. This implies:

$$\tau^{1/p_v} = \sum_{w \in \mathcal{V}} p_w \tau^{1/p_w}$$

The right-hand side is a constant across all tokens, whereas the left-hand side strictly depends on p_v . This equality holds if and only if all tokens have the exact same probability $p_v = 1/|\mathcal{V}|$. $\square$

Remark 2. The distortion shifts mass from high-confidence tokens (large p_v , frequently skipped since τ^{1/p_v} is large) toward low-confidence tokens (small p_v , rarely skipped). For example, with $p_1 = 0.9$, $p_2 = 0.1$, and $\tau = 0.5$: the output probabilities become (0.858, 0.142) instead of (0.9, 0.1). In practice, τ is small (e.g., $\tau = 0.1$), so the distortion is mild.

Proposition 12 (Bound on expected score under adaptive skip). *Under adaptive skip with threshold $\tau \in [0, 1]$ (the watermark is disabled when $R_{V^*}^{(t)} < \tau$), the expected score satisfies:*

$$\mathbb{E}[S_T] \geq T + \left(\frac{\pi^2}{6} - 1 \right) H_T + \ln(1 - \tau) \sum_{t=1}^T \tau^{1/p_t} \quad (21)$$

The correction term is always non-positive, vanishing as $\tau \rightarrow 0$.

Proof. We condition on the identity of the selected token. By [Proposition 1](#), $\mathbb{P}(V^* = v) = p_v$. By [Corollary 1](#), conditioned on $V^* = v$, the PRF value $R_v \sim \text{Beta}(1/p_v, 1)$ with density $f(r) = \frac{1}{p_v} r^{1/p_v - 1}$ and CDF $F(r) = r^{1/p_v}$. The skip condition $R_v < \tau$ therefore has conditional probability $\mathbb{P}(R_v < \tau \mid V^* = v) = \tau^{1/p_v}$. This decreases with entropy: for confident tokens ($p_v \rightarrow 1$), $\tau^{1/p_v} \rightarrow \tau$ (frequent skipping); for unlikely tokens ($p_v \rightarrow 0$), $\tau^{1/p_v} \rightarrow 0$ (rare skipping).

We now bound $\mathbb{E}[s_t \mid V^* = v]$. Decomposing over the skip decision:

$$\mathbb{E}[s_t \mid V^* = v] = \underbrace{\mathbb{E}[-\ln(1 - R_v) \cdot \mathbf{1}_{R_v \geq \tau} \mid V^* = v]}_{\text{not skipped: use watermarked token}} + \underbrace{\mathbb{E}[-\ln(1 - R_{X_t}) \cdot \mathbf{1}_{R_v < \tau} \mid V^* = v]}_{\text{skipped: resample } X_t \sim \mathbf{p}}$$

The first term integrates the score over the non-skip region using the conditional density of R_v :

$$\mathbb{E}[-\ln(1 - R_v) \cdot \mathbf{1}_{R_v \geq \tau} \mid V^* = v] = \int_{\tau}^1 \frac{-\ln(1 - r)}{p_v} r^{1/p_v - 1} dr$$

For the second term, the replacement token $X_t \sim \mathbf{p}$ is drawn with independent randomness, but its PRF value R_{X_t} comes from the *same* realization $\mathbf{R}$, so we cannot claim its expected score is 1 (see [Remark 4](#)). Since $-\ln(1 - R_{X_t}) \geq 0$, the second term is non-negative, so:

$$\mathbb{E}[s_t \mid V^* = v] \geq \int_{\tau}^1 \frac{-\ln(1 - r)}{p_v} r^{1/p_v - 1} dr = \mathcal{H}_{1/p_v} - \int_0^{\tau} \frac{-\ln(1 - r)}{p_v} r^{1/p_v - 1} dr$$

where we used $\int_\tau^1 = \int_0^1 - \int_0^\tau$ and $\int_0^1 \frac{-\ln(1-r)}{p_v} r^{1/p_v-1} dr = \mathcal{H}_{1/p_v}$. Since $-\ln(1-r) \leq -\ln(1-\tau)$ for $r \in [0, \tau]$:

$$\begin{aligned} \int_0^\tau \frac{-\ln(1-r)}{p_v} r^{1/p_v-1} dr &\leq \int_0^\tau \frac{-\ln(1-\tau)}{p_v} r^{1/p_v-1} dr \\ &= \frac{-\ln(1-\tau)}{p_v} \int_0^\tau r^{1/p_v-1} dr \\ &= \frac{-\ln(1-\tau)}{p_v} \left[p_v \cdot r^{1/p_v} \right]_0^\tau \\ &= \frac{-\ln(1-\tau)}{p_v} (p_v \cdot \tau^{1/p_v} - 0) \\ &= -\ln(1-\tau) \cdot \tau^{1/p_v} \end{aligned}$$

and therefore $\mathbb{E}[s_t \mid V^* = v] \geq \mathcal{H}_{1/p_v} + \tau^{1/p_v} \ln(1-\tau)$. Since this holds for every v , it holds for the realized token probability $p_t = p_{V^*}$. Summing over T steps and applying the standard bound (Proposition 3) to $\sum_t \mathcal{H}_{1/p_t} \geq T + (\frac{\pi^2}{6} - 1)H_T$ gives the result. $\square$

Remark 3. The penalty $\ln(1-\tau) \sum_t \tau^{1/p_t}$ is always non-positive (since $\ln(1-\tau) < 0$), confirming that skipping can only reduce the detection signal. For small τ (e.g., $\tau = 0.1$), the penalty is negligible: τ^{1/p_t} is small for all but deterministic tokens ($p_t \approx 1$), and those tokens carry no watermark signal anyway ($\mathcal{H}_1 = 1$, equal to the null baseline). The bound is conservative because we dropped the skip contribution entirely; in practice, skipped tokens still contribute positively to the score.

Remark 4 (Skip contribution). A tempting (but incorrect) approach is to claim that skipped tokens contribute expected score 1, arguing that the replacement token $X_t \sim \mathbf{p}$ is drawn independently and therefore its PRF value R_{X_t} is uniform. This would yield the decomposition:

$$\mathbb{E}[s_t] = \int_\tau^1 \frac{-\ln(1-r)}{p_t} r^{1/p_t-1} dr + \tau^{1/p_t} \cdot 1$$

leading to a correction $\tau^{1/p_t}(1 + \ln(1-\tau))$ that is *positive* for $\tau < 1 - 1/e$ —implying that skipping *improves* detection, which is impossible.

The error is that while X_t is drawn independently of $\mathbf{R}$, the PRF value $R_{X_t} = \mathbf{R}[X_t]$ shares the *same* realization $\mathbf{R}$. Since the skip event $\{R_{V^*} < \tau\}$ constrains $\mathbf{R}$ (the winning PRF value is low), the conditional expectation $\mathbb{E}[-\ln(1-R_{X_t}) \mid R_{V^*} < \tau] \neq 1$. A simple counterexample: for a deterministic token ($p_t = 1$), there is only one possible token, so skipping changes nothing and $\mathbb{E}[s_t] = \mathcal{H}_1 = 1$. Yet the incorrect formula gives $1 + \tau(1 + \ln(1-\tau)) > 1$.

C.5 Entropy-Normalized Adaptive Skip

This variant of adaptive skip replaces the fixed threshold τ with an entropy-dependent threshold $\tau^{p_{V^*}}$, which ensures every token is skipped with exactly the same probability τ regardless of its confidence level. This restores the distortion-free property lost by standard adaptive skip.

For a target skip rate $\tau \in (0, 1)$, the watermark is now disabled and the token is resampled from $\mathbf{p}$ if:

$$R_{V^*} < \tau^{p_{V^*}}$$

Proposition 13 (Distortion-freeness of entropy-normalized skip). *The entropy-normalized adaptive skip mechanism is distortion-free, i.e., $\mathbb{P}(\text{output} = v) = p_v$ for all $v \in \mathcal{V}$.*

Proof. We first evaluate the conditional probability of a skip occurring given that token v was initially selected. By Corollary 1, $R_v \mid V^* = v \sim \text{Beta}(1/p_v, 1)$, which has the cumulative distribution function $F(r) = r^{1/p_v}$. Therefore, the conditional skip probability is:

$$\mathbb{P}(\text{skip} \mid V^* = v) = \mathbb{P}(R_v < \tau^{p_v} \mid V^* = v) = (\tau^{p_v})^{1/p_v} = \tau$$

Because this conditional probability is exactly τ for *every* token in the vocabulary, the unconditional probability of a skip is also exactly τ . Indeed, by the law of total probability:

$$\mathbb{P}(\text{skip}) = \sum_{w \in \mathcal{V}} \mathbb{P}(\text{skip} \mid V^* = w) \mathbb{P}(V^* = w) = \sum_{w \in \mathcal{V}} \tau \cdot p_w = \tau \sum_{w \in \mathcal{V}} p_w = \tau$$

The total marginal probability of outputting token v can then be found by partitioning over the two mutually exclusive generation paths (whether a skip occurs or not):

$$\begin{aligned} \mathbb{P}(\text{output} = v) &= \mathbb{P}(\text{output} = v \cap \text{not skipped}) + \mathbb{P}(\text{output} = v \cap \text{skip}) \\ &= \mathbb{P}(V^* = v \cap R_{V^*} \geq \tau^{p_{V^*}}) + \mathbb{P}(\text{skip}) \cdot \mathbb{P}(X_t = v) \\ &= \mathbb{P}(V^* = v) \cdot \mathbb{P}(R_v \geq \tau^{p_v} \mid V^* = v) + \mathbb{P}(\text{skip}) \cdot \mathbb{P}(X_t = v) \end{aligned}$$

We know the unconditional probability of a skip is τ , so the conditional probability of not skipping is $1 - \tau$. Furthermore, the replacement token X_t is sampled from the original distribution independently of the skip event, so $\mathbb{P}(X_t = v) = p_v$. Substituting these values yields:

$$\begin{aligned} \mathbb{P}(\text{output} = v) &= p_v \cdot (1 - \tau) + \tau \cdot p_v \\ &= p_v - p_v \tau + p_v \tau \\ &= p_v \end{aligned}$$

Thus, the marginal distribution is perfectly preserved, making the entropy-normalized mechanism distortion-free. $\square$

Proposition 14 (Bound on expected score under entropy-normalized skip). *Under the entropy-normalized adaptive skip with target skip rate $\tau \in (0, 1)$, the expected score satisfies:*

$$\mathbb{E}[S_T] \geq T + \left(\frac{\pi^2}{6} - 1 \right) H_T + \tau \sum_{t=1}^T \ln(1 - \tau^{p_t}) \quad (22)$$

Proof. We condition on the identity of the selected token $V^* = v$. We decompose the expected score into the non-skipped and skipped cases:

$$\mathbb{E}[s_t \mid V^* = v] = \mathbb{E}[-\ln(1 - R_v) \cdot \mathbf{1}_{R_v \geq \tau^{p_v}} \mid V^* = v] + \mathbb{E}[-\ln(1 - R_{X_t}) \cdot \mathbf{1}_{R_v < \tau^{p_v}} \mid V^* = v]$$

As discussed in [Remark 4](#), the replacement token X_t relies on the same PRF realization $\mathbf{R}$, so its contribution is difficult to isolate but strictly non-negative. Dropping the second term provides a conservative lower bound:

$$\mathbb{E}[s_t \mid V^* = v] \geq \int_{\tau^{p_v}}^1 \frac{-\ln(1 - r)}{p_v} r^{1/p_v - 1} dr = \mathcal{H}_{1/p_v} - \int_0^{\tau^{p_v}} \frac{-\ln(1 - r)}{p_v} r^{1/p_v - 1} dr$$

Since the function $-\ln(1 - r)$ is monotonically increasing, for $r \in [0, \tau^{p_v}]$, we have $-\ln(1 - r) \leq -\ln(1 - \tau^{p_v})$. We can bound the subtracted integral:

$$\begin{aligned} \int_0^{\tau^{p_v}} \frac{-\ln(1 - r)}{p_v} r^{1/p_v - 1} dr &\leq -\ln(1 - \tau^{p_v}) \int_0^{\tau^{p_v}} \frac{1}{p_v} r^{1/p_v - 1} dr \\ &= -\ln(1 - \tau^{p_v}) \left[r^{1/p_v} \right]_0^{\tau^{p_v}} \\ &= -\ln(1 - \tau^{p_v}) (\tau^{p_v})^{1/p_v} \\ &= -\tau \ln(1 - \tau^{p_v}) \end{aligned}$$

Substituting this back yields:

$$\mathbb{E}[s_t \mid V^* = v] \geq \mathcal{H}_{1/p_v} + \tau \ln(1 - \tau^{p_v})$$

Since this inequality holds for any chosen v , it holds for the realized token probability p_t . Summing over the sequence of T tokens and applying the standard Gumbel bound ([Proposition 3](#)) gives:

$$\mathbb{E}[S_T] \geq \sum_{t=1}^T \mathcal{H}_{1/p_t} + \tau \sum_{t=1}^T \ln(1 - \tau^{p_t}) \geq T + \left(\frac{\pi^2}{6} - 1\right) H_T + \tau \sum_{t=1}^T \ln(1 - \tau^{p_t})$$

The correction term is strictly non-positive because $\tau^{p_t} \in (0, 1)$, meaning $\ln(1 - \tau^{p_t}) < 0$. This accurately reflects the expected loss in signal when skipping exactly τ fraction of the tokens. $\square$

Remark 5 (Skip behavior and score penalty). Unlike standard adaptive skip where the skip probability τ^{1/p_v} depends on token confidence (skipping high-confidence tokens more often), the entropy-normalized threshold τ^{p_v} ensures a *uniform* skip rate of exactly τ for all tokens regardless of their probability. However, the per-token score penalty $\tau \ln(1 - \tau^{p_t})$ still varies with entropy:

- For high-confidence tokens ($p_t \rightarrow 1$): the penalty approaches $\tau \ln(1 - \tau)$, which is mild. These tokens contribute little watermark signal anyway ($\mathcal{H}_1 = 1$, equal to the null baseline), so skipping them has minimal impact.
- For low-confidence tokens ($p_t \rightarrow 0$): the threshold $\tau^{p_t} \rightarrow 1$, making the penalty bound $\tau \ln(1 - \tau^{p_t}) \rightarrow -\infty$, making the bound effectively useless. Such tokens occur rarely ($\mathbb{P}(V^* = v) = p_v$), so their contribution to the total penalty is attenuated by their low occurrence frequency.

The mechanism thus achieves distortion-freeness while concentrating the detection penalty on tokens that either carry little signal (high-confidence) or appear rarely (low-confidence), preserving most of the watermark power from medium-entropy tokens.

D Fast Localization and Statistical Penalties

In practical settings, the exact start and end indices of a watermarked insertion are unknown. Our objective is to determine a set of disjoint watermarked intervals $\{[a_1, b_1], \dots, [a_y, b_y]\}$. A naive exhaustive search over all possible intervals in a sequence of length n requires evaluating $\binom{n}{2} \approx n^2/2$ windows. This $\mathcal{O}(n^2)$ search space not only introduces severe computational bottlenecks but also imposes an insurmountable statistical penalty via multiple-testing correction, as false positives become significantly more likely as the number of tested hypotheses grows. To optimize both computational and statistical efficiency, we utilize a geometric cover search space ([Kirchenbauer et al., 2023b](#)) combined with a fast two-stage extraction pipeline and rigorous Bonferroni correction.

D.1 The Geometric Cover Search

To avoid testing $\mathcal{O}(n^2)$ intervals, we constrain our search to a dyadic grid of windows. We define a set of window lengths $L \in \{L_0, 2L_0, 4L_0, \dots, 2^{\lceil \log_2 n \rceil}\}$, where $L_0 = 2^{\lceil \log_2 L_{\min} \rceil}$ is the smallest power of two at least as large as the minimum zone length $L_{\min}$. For each length L , we slide the window across the text with a stride of $L/2$.

This geometric grid guarantees that any arbitrary watermarked region of length $L^* \geq L_{\min}$ will be at least 50% covered by at least one grid window. The total number of candidate windows M in this grid is strictly bounded:

$$M = \sum_{k=\lceil \log_2 L_{\min} \rceil}^{\lceil \log_2 n \rceil} \left\lfloor \frac{n - 2^k}{2^{k-1}} \right\rfloor + 1 \approx \frac{4n}{L_0} \quad (23)$$

By restricting the search to $M \approx \mathcal{O}(n/L_{\min})$ windows, we reduce the hypothesis space by orders of magnitude, dramatically lowering the statistical tax required to claim significance.

D.2 Fast Two-Stage Pipeline and Greedy Extraction

Evaluating the rigorous, entropy-weighted Gamma distribution for all M windows can be computationally heavy. To process arbitrarily large documents efficiently, we utilize a two-stage pipeline:

1. **Fast Filtering:** We pre-calculate prefix sums of the unweighted raw scores s_i . The sum for any candidate interval in the grid can then be computed in $\mathcal{O}(1)$ time. We select the top candidates based on these raw sums.
2. **Rigorous Scoring:** For the most promising candidates, we compute the exact entropy-weighted moment-matched Gamma p -value p_{raw} (as defined in Section 3.2).

To extract multiple zones, we proceed greedily. We find the window I^* with the most significant p_{raw} . If its penalized significance (accounting for the search tax) is high enough, we flag it as watermarked, mask its tokens (setting their scores to zero), and repeat the search on the residual text. We aggregate disjoint intervals until the combined p -value fails to overcome the multiple-testing threshold, up to a maximum of Y_{max} zones.

D.3 The Bonferroni Tax and False Positive Guarantee

Evaluating M intervals introduces the multiple comparisons problem. To maintain a strict family-wise error rate (FWER) ϵ under the null hypothesis $\mathcal{H}_0$, we apply a union bound.

For a single-zone search, the Bonferroni correction factor is simply M . For a multi-zone search identifying y disjoint regions, we must account for the number of ways to choose y windows from the grid, $\binom{M}{y}$, as well as the optimization over $y \in [1, Y_{\text{max}}]$. The corrected p -value in log-space is:

$$\ln p_{\text{corrected}} = \ln p_{\text{raw}} + \ln \binom{M}{y} + \ln Y_{\text{max}} \quad (24)$$

Under $\mathcal{H}_0$, the probability that the most significant window combination exceeds our threshold is strictly bounded:

$$\mathbb{P} \left(\bigcup_{i=1}^K \left\{ p_i \leq \frac{\epsilon}{K} \right\} \mid \mathcal{H}_0 \right) \leq \sum_{i=1}^K \mathbb{P} \left(p_i \leq \frac{\epsilon}{K} \mid \mathcal{H}_0 \right) = K \cdot \frac{\epsilon}{K} = \epsilon \quad (25)$$

where K represents the total number of tested hypotheses in the search space. This guarantees that the probability of falsely accusing an entirely human-written text remains $\leq \epsilon$, regardless of document length.

D.4 Asymptotic Power Comparison: Global vs. Localized Detection

We define the crossover point where the localized multi-zone test yields a stronger rejection of $\mathcal{H}_0$ than the global test. Let n be the document length, and $\rho \in (0, 1]$ be the fraction of tokens that are watermarked ($w = \rho n$).

Setup and Approximation. Let the weighted token score $\tilde{s}_i$ have mean μ_0 and variance σ^2 under $\mathcal{H}_0$. Under $\mathcal{H}_1$, the mean shifts to $\mu_w > \mu_0$. Let $\delta = (\mu_w - \mu_0)/\sigma$ be the per-token signal-to-noise ratio. Using a Gaussian tail approximation, the log p -value of a Z-score is $\ln p \approx -\frac{1}{2}Z^2$. We define $\Delta^2 = \delta^2/2$ as the expected log p -value accumulation rate per watermarked token.

Power of the Global Test. The global test evaluates all n tokens. The expected Z-score is:

$$Z_{\text{global}} = \frac{\rho n \sigma \delta}{\sigma \sqrt{n}} = \rho \delta \sqrt{n} \implies \mathbb{E}[\ln p_{\text{global}}] \approx -\rho^2 n \Delta^2 \quad (26)$$

The signal strength scales quadratically with ρ ; the $(1 - \rho)n$ human tokens contribute no signal but inflate the variance, diluting the test.

Power of the Localized Test. Assuming a localized test correctly isolates the ρn watermarked tokens into y zones, the variance is reduced to the watermarked subset $\rho n \sigma^2$. The expected raw log p -value is:

$$Z_{\text{local}} = \frac{\rho n \sigma \delta}{\sigma \sqrt{\rho n}} = \delta \sqrt{\rho n} \implies \mathbb{E}[\ln p_{\text{local, raw}}] \approx -\rho n \Delta^2 \quad (27)$$

Table 6 Benchmark accuracy (%) across 5 random seeds (non-watermarked) or 5 secret keys (watermarked). We report Mean $\pm$ Std to quantify generation variance. “Dedup” refers to n -gram deduplication at generation-time (see [Remark 1](#)). Differences between conditions fall within one standard deviation, indicating no systematic degradation from watermarking.

Benchmark	No Watermark	WM (no dedup)	WM (dedup)
AIME	41.0 $\pm$ 1.2	40.6 $\pm$ 1.2	40.8 $\pm$ 0.9
GSM8K	95.9 $\pm$ 0.3	95.6 $\pm$ 0.3	95.9 $\pm$ 0.3
HumanEval	97.1 $\pm$ 0.9	97.6 $\pm$ 2.4	97.8 $\pm$ 0.7
MBPP	50.2 $\pm$ 0.6	49.8 $\pm$ 0.4	49.7 $\pm$ 0.6
MMLU	87.6 $\pm$ 0.5	87.1 $\pm$ 1.6	87.8 $\pm$ 0.6

Accounting for the combinatorial tax $\ln \binom{n}{2y} \approx 2y \ln n$, the penalized localized score is:

$$\mathbb{E}[\ln p_{\text{local, final}}] \approx -\rho n \Delta^2 + 2y \ln n \quad (28)$$

The Crossover Point. The localized test dominates when $\mathbb{E}[\ln p_{\text{local, final}}] < \mathbb{E}[\ln p_{\text{global}}]$:

$$-\rho n \Delta^2 + 2y \ln n < -\rho^2 n \Delta^2 \quad (29)$$

$$n \Delta^2 (\rho - \rho^2) > 2y \ln n \quad (30)$$

$$\rho(1 - \rho) > \frac{2y \ln n}{n \Delta^2} \quad (31)$$

This inequality demonstrates that localized detection is optimal when the signal is sufficiently concentrated (low ρ) such that the variance reduction from excluding human tokens outweighs the logarithmic search tax.

E Additional Experiments and Details

E.1 Benchmark Variance Analysis

Evaluating LLM performance on benchmarks with chain-of-thoughts involves variance due to the stochastic generation, and the final answer extraction heuristics (e.g., regex-based parsing for numbers or letters, or code execution for programming tasks). To quantify this variance and assess whether watermarking introduces systematic degradation or improvement, we re-ran a subset of benchmarks with multiple random seeds for non-watermarked generation and multiple secret keys for watermarked generation.

Experimental Setup. We use Qwen 3.5-72B with reasoning enabled (reasoning temperature 0.6, top- $p = 0.95$, max 3,000 reasoning tokens). We evaluate on five benchmarks: AIME (math), GSM8K (math), HumanEval (code), MBPP (code), and MMLU (multiple choice). For non-watermarked generation, we use 5 different random seeds. For watermarked generation, we use the same values as secret keys, with both n -gram deduplication enabled and disabled (see [Remark 1](#)): when enabled, watermark contexts that have already appeared in the generation fall back to vanilla sampling instead of watermarked sampling.

Results. The standard deviation across seeds/keys ranges from 0.3% to 2.4%, depending on the benchmark and condition. Code benchmarks exhibit variance due to the binary nature of test execution and sensitivity to minor formatting differences. Crucially, the differences between watermarked and non-watermarked conditions fall within approximately one standard deviation, indicating no systematic performance degradation from watermarking.

Effect of n -Gram Deduplication. Enabling n -gram deduplication (falling back to vanilla sampling for repeated context windows) tends to produce lower variance, particularly visible on MMLU (0.6 vs 1.6 std) and HumanEval (0.7 vs 2.4 std). This is consistent with the observation that repeated n -gram

Table 7 Watermark detection performance on multilingual QA.

Metric	English	Arabic	Chinese	Hindi	Japanese	Overall
TPR@0.1%	53.6%	83.3%	79.5%	59.0%	51.0%	63.3%
Median $\log_{10} p$	-3.15	-5.23	-4.62	-3.51	-3.04	-3.72

contexts in reasoning chains can lead to more deterministic (and potentially repetitive) generation patterns when not deduplicated.

E.2 Multilingual QA

This section provides the full experimental setup for the multilingual question-answering evaluation. The same dataset and generation pipeline are used for both the watermark detection analysis below and the human preference evaluation in [subsection E.3](#).

Experimental Configuration. We use GPT-OSS-20B with reasoning enabled (max 2,000 reasoning tokens) and watermarking applied to the reasoning trace. Generation uses temperature 0.7, top- $p = 0.95$, and a maximum length of 4,096 tokens. The watermark employs Gumbel-Max with 3-gram context, dual-key early fusion ($\alpha = 0.1$), and a fixed secret key.

Datasets. We evaluate on 6,000 question-answer pairs across five languages: English (2,000 samples from ELI5), and Arabic, Chinese, Hindi, and Japanese (1,000 samples each from CaLMQA ([Arora et al., 2025](#))).

System Prompt. The following system prompt was used for all languages:

“You are answering questions. Give a clear, concise explanation in plain language. Answer in the same language as the question. Keep your answer to 50–150 words. No bullet points, headers, or markdown formatting—just natural prose.”

Watermark Detection Results. Arabic and Chinese show strongest detection, which is likely due to higher per-token entropy. Japanese shows lowest detection (51%) due to the more constrained vocabulary and lower entropy in CJK scripts.

Statistical Tests for Differences. We apply McNemar’s test ([McNemar, 1947](#)) to assess whether watermarking systematically affects script consistency or refusal rates. For script consistency, we observe 52 discordant pairs where WM was wrong but Non-WM was correct, versus 39 where Non-WM was wrong but WM was correct; with continuity correction, this yields $\chi^2 = 1.58$ and $p = 0.21$. For refusal rates, we find 21 pairs where WM refused but Non-WM answered, versus 15 where Non-WM refused but WM answered, giving $\chi^2 = 0.69$ and $p = 0.41$. Both p -values are well above the significance threshold ($\alpha = 0.05$), indicating that watermarking does not systematically increase script errors or refusals.

E.3 Human Evaluation Details

This section provides methodology and detailed results for the human evaluation study summarized in [subsection 4.4](#). The experimental setup (model, datasets, generation parameters) is shared with the multilingual QA experiment described in [subsection E.2](#).

Preference Distribution. [Table 8](#) shows the complete four-class preference breakdown before merging tie categories. Annotators chose among: *A is preferred*, *B is preferred*, *Both equally good*, and *Both equally bad*. We aggregate via majority vote (at least 2/3 annotators agree); samples with a three-way split (one vote per distinct category) are assigned to “Tie.” For the final analysis, “Both Good,” “Both Bad,” and splits are merged into a single Tie category.

Table 8 Full four-class preference breakdown (majority vote, 3 annotators per sample). Split: items where no majority exists (three-way tie), counted as Tie in the final analysis.

Language	N	Prefer WM	Prefer Base	Both Good	Both Bad	Split
English	2,000	150	120	1,482	92	156
Arabic	1,000	198	184	168	287	163
Chinese	1,000	90	68	514	272	56
Hindi	1,000	98	82	435	278	107
Japanese	1,000	136	137	275	228	224
Overall	6,000	672	591	2,874	1,157	706

Table 9 TOST equivalence test results ($\Delta = 5\%$, $\alpha = 0.05$). Proportions computed over all N samples. 90% CI: Wald interval for the difference $P(\text{WM}) - P(\text{Base})$.

Language	N	$\hat{d}$	90% CI	p_{TOST}	Result
English	2,000	+1.50%	[+0.2%, +2.9%]	< 0.001	Equivalent
Arabic	1,000	+1.40%	[−1.8%, +4.6%]	0.033	Equivalent
Chinese	1,000	+2.20%	[+0.1%, +4.3%]	0.013	Equivalent
Hindi	1,000	+1.60%	[−0.6%, +3.8%]	0.006	Equivalent
Japanese	1,000	−0.10%	[−2.8%, +2.6%]	0.002	Equivalent
Overall	6,000	+1.35%	[+0.4%, +2.3%]	< 0.001	Equivalent

Net Win Rate. We define the *net win rate* as

$$\text{Net Win Rate} = \frac{n_{\text{WM}} - n_{\text{Base}}}{N}, \quad (32)$$

where n_{WM} and n_{Base} are the number of samples where the watermarked or baseline response was preferred (by majority vote), and N is the total number of samples including ties. The overall net win rate is +1.35% (672 WM wins vs. 591 Base wins out of 6,000 samples), indicating a negligible advantage for watermarked outputs.

Binomial Test. Among decisive (non-tie) samples, we test the null hypothesis $H_0 : P(\text{WM preferred}) = 0.5$ using a two-sided exact binomial test. No individual language reaches significance at $\alpha = 0.05$ (English: $p = 0.08$; Arabic: $p = 0.51$; Chinese: $p = 0.09$; Hindi: $p = 0.26$; Japanese: $p = 1.00$). The overall pooled test yields $p = 0.02$, which does not survive Bonferroni correction for six comparisons ($\alpha/6 = 0.008$). Importantly, the direction of the marginal effect favors the watermark, indicating no quality degradation.

Equivalence Testing (TOST with Ties). To establish imperceptibility—rather than merely failing to detect a difference—we apply the Two One-Sided Tests (TOST) procedure (Schuirmann, 1987). We test:

$$H_0: |P(\text{WM preferred}) - P(\text{Base preferred})| \geq \Delta \quad \text{vs.} \quad H_1: |P(\text{WM preferred}) - P(\text{Base preferred})| < \Delta \quad (33)$$

where proportions are computed over *all* N samples (including ties in the denominator). This formulation is more powerful than restricting to decisive samples, because ties represent direct evidence of imperceptibility (the annotator could not distinguish between outputs) and contribute to the sample size.

Let $\hat{d} = \hat{p}_{\text{WM}} - \hat{p}_{\text{Base}}$ with standard error $\text{SE} = \sqrt{(\hat{p}_{\text{WM}} + \hat{p}_{\text{Base}} - \hat{d}^2)/N}$. The TOST procedure computes two one-sided z -tests: $z_1 = (\hat{d} - \Delta)/\text{SE}$ and $z_2 = (\hat{d} + \Delta)/\text{SE}$, and rejects H_0 when $\max(\Phi(z_1), 1 - \Phi(z_2)) < \alpha$.

Table 9 reports results for $\Delta = 5\%$. Equivalence is established for all five languages and overall, confirming that the preference difference is bounded within ± 5 percentage points.

Table 10 Inter-annotator agreement statistics by language (four-class scale).

Language	Unanimous Rate	Majority ($\geq 2/3$)	Pairwise Agreement
English	54.0%	92.2%	0.667
Arabic	23.9%	83.7%	0.438
Chinese	48.5%	94.4%	0.638
Hindi	37.0%	89.3%	0.544
Japanese	17.0%	77.6%	0.372
Overall	39.1%	88.2%	0.554

On Trinomial Tests. An alternative approach is the trinomial test for paired data with ties (Bian et al., 2011), which models the three-category distribution (WM, Base, Tie) directly. We experimented with this approach but found that the chi-square statistic converges rapidly with the number of ties: once more than a handful of ties are present, the p -value stabilizes to the second decimal place and equals the standard binomial test on decisive samples. Since 79% of our samples are ties, the trinomial test provides no additional discriminative power, which motivates our use of the TOST procedure that explicitly leverages ties as evidence of imperceptibility.

Inter-Annotator Agreement. We measure agreement using two metrics: (i) unanimous agreement rate (fraction of samples where all 3 annotators selected the same four-class option), and (ii) mean pairwise agreement (average fraction of annotator pairs that agree on the four-class label). Table 10 shows that agreement varies by language, with English and Chinese exhibiting the highest consistency. The lower agreement rates for Arabic and Japanese may reflect the inherent subjectivity of quality judgments and cultural differences in evaluation norms.

Text Quality Metrics. We compare objective text quality metrics between watermarked and non-watermarked responses. Mean response lengths are nearly identical (WM: 176.8 ± 119.2 tokens; Non-WM: 177.9 ± 122.9 tokens), and repetition rates (measured as the fraction of repeated n -grams) show no significant difference. This confirms that the watermarking process does not systematically affect surface-level text characteristics.

E.4 Learnability Experimental Details

Models & Dataset. The teacher is DeepSeek-R1-Distill-Qwen-14B (Guo et al., 2025), an R1-style reasoning model that produces long chain-of-thought traces enclosed in `<think>` tags, and the student is Qwen2.5-3B (Team, 2024). We train on a subset of 5,000 problems drawn from OpenR1-Math-220k (Hugging Face, 2025), curated via a three-stage pipeline: (i) malformed or incomplete problems are removed; (ii) only problems that the student model fails to solve are retained, ensuring the training data teaches new capabilities; (iii) diversity sampling across 14 math categories with a 15% cap per category prevents overrepresentation of any single topic.

Watermarked Trace Generation. We compare the three sampling-based methods introduced in subsection 4.1: *Gumbel-Max* (Aaronson and Kirchner, 2023), *TextSeal* (dual-key routing probability $\alpha = 0.1$), and *SynthID* (Dathathri et al., 2024) (plus an unwatermarked control), all with watermark context window $k = 3$. Secret keys are calibrated per method via a Kolmogorov–Smirnov test to ensure uniform PRF hashes on unwatermarked text as done in Fernandez et al. (2025). The teacher generates 5,000 solutions using vLLM (Kwon et al., 2023) with flash-attention-2 on 4×H200 GPUs (tensor parallel), with $T = 1.0$, top- $p = 0.95$, and max 8,192 generated tokens.

Quality Filtering. Each teacher trace passes through four sequential filters (the first failure rejects the trace): (i) *think closure*—the trace must contain a closing `</think>` tag; (ii) *boxed presence*—the trace must include a `\boxed{...}` final-answer pattern (skipped for multiple-choice datasets); (iii) *repetition detection*—a sampled sliding-window check (window size 100 characters, ~ 200 evenly spaced samples) rejects any trace in which a substring occurs ≥ 3 times (responses ≤ 200 characters auto-pass);

Table 11 Full learnability statistics (OpenR1, $N=5,000$ prompts). Teacher $-\log_{10}(p)$ is the detection power of the watermark in the teacher’s own traces (mean and median across individual traces). Student $-\log_{10}(p)$ is the pooled detection power after distillation (original setting, all retained traces). [†]TextSeal uses entropy-weighted scoring.

Method	Retained Traces	Pass Rate	Teacher $-\log_{10}(p)$		Student $-\log_{10}(p)$
			Mean	Median	
Gumbel-Max	1,991	39.8%	14.89	9.09	24.80
TextSeal	2,352	47.0%	33.15 [†]	27.50 [†]	35.82 [†]
SynthID	2,408	48.2%	14.39	12.12	13.54
Control	2,400	48.0%	0.39	0.25	—

(iv) *answer verification*—the extracted answer is compared to the gold answer using the `math_verify` library in a fail-open mode: if either side fails to parse, the trace is kept rather than rejected.

Student Fine-Tuning. The student is fine-tuned on the filtered traces using LoRA (Hu et al., 2022) (rank 128, scaling factor 128, dropout 0.05) with learning rate 2×10^{-5} and 3 epochs. The loss is computed over the full teacher response (both the reasoning trace and the final answer) while the prompt tokens are masked out.

Watermark Detection. We evaluate watermark transfer using the *open-model* radioactivity test of Sander et al. (2024, 2025). The test operates in a *teacher-forcing* setup: each training trace is fed into the student model, and the student’s top-1 prediction $\hat{x}^{(t)} = \arg \max_{v \in \mathcal{V}} P_{\theta}(v \mid x_{<t})$ is recorded at every response position t . Crucially, we score the student’s *predictions* rather than newly generated text: this isolates the watermark signal from confounding factors such as sampling noise and generation quality, while requiring only a single forward pass over the existing traces rather than expensive autoregressive generation. If the student has internalized the watermark’s token preferences during fine-tuning, its top-1 predictions will be systematically biased toward high-PRF tokens—even without access to the secret key.

We score each prediction using the watermark’s PRF: $R_t = \text{PRF}(\hat{x}^{(t)}, \mathbf{w}_t, K)$, where $\mathbf{w}_t = (x^{(t-k)}, \dots, x^{(t-1)})$ is the trigram context window of *teacher* tokens preceding position t (as defined in section 2). Within each trace, each context window is scored only once; across traces, all (context, predicted token) pairs are pooled and deduplicated so that repeated tuples are counted only once, satisfying the independence assumption required by the statistical test (Fernandez et al., 2023). This yields ~ 1.4 – 2.2 M unique scored tokens per method.

For Gumbel-Max, a single pooled Gamma test produces the p -value: we compute $s_t = -\ln(1 - R_t)$ for each unique pair and sum over all n unique scored tokens to obtain $S_n = \sum_{t=1}^n s_t$, which under $\mathcal{H}_0$ follows $\Gamma(n, 1)$ (Proposition 2). For TextSeal, we use the entropy-weighted early-fusion score with $w_i^{\text{ent}} = \sqrt{\hat{H}_i}$ weighting (subsection 3.2), where entropy is estimated from the student model’s forward pass, and compute the p -value via the moment-matched Gamma approximation of Equation 6; the choice of weighting function is validated by the ablation in Figure 9. For SynthID, we apply the frequentist test described in subsection 4.1, computing a depth-weighted Z-score over the tournament layers.

Teacher Trace Quality. Pass rates are 48% for the control, 48.2% for SynthID, 47% for TextSeal, and 39.8% for Gumbel-Max, yielding 2,400, 2,408, 2,352, and 1,991 well-formed traces respectively. Gumbel-Max traces are also notably shorter on average ($\sim 2,400$ response tokens vs. $\sim 3,300$ – $3,500$ for other methods), because its deterministic argmax selection causes more repetition loops at $T=1.0$; the filter removes these long repetitive traces, leaving only shorter clean ones. As a result, the student is fine-tuned on different amounts of data across configurations; we do not normalize for this, as the variation in sample count is modest ($\sim 20\%$).

Controlled Comparisons. The results above are obtained with each method’s full set of well-formed traces, which differ in count (1,991–2,408) and average length (Gumbel-Max traces average $\sim 2,400$

tokens vs. $\sim 3,300$ – $3,500$ for other methods). To rule out training data volume as a confound, we repeat the experiment under two controlled conditions (Figure 8): (i) *equal traces*, where each method uses exactly 1,991 traces (the Gumbel-Max minimum, randomly subsampled for the other methods), and (ii) *equal tokens*, where each method is allocated ~ 15.1 M characters (subsampling traces for methods with more tokens, using all available traces for Gumbel-Max). Under equal traces, TextSeal achieves the highest student accuracy (81.0%), followed by SynthID and Control (78.8% each) and Gumbel-Max (77.7%). Under equal tokens, the spread narrows (79.7%/78.6%/79.6%/77.6% for TextSeal/Gumbel-Max/SynthID/Control). In both settings all watermarked students substantially improve over the pre-training baseline (64.5%). Detection results confirm that all three watermarks remain strongly detectable under both controls, validating that the learnability conclusions of Figure 8 are not artifacts of unequal training data volume.

Entropy Weighting Ablation. Each weighting variant in Figure 9 computes the weighted statistic $S_{\text{combined}} = \sum_{i=1}^n w_i^{\text{ent}} \cdot s_i$, where s_i is TextSeal’s early-fusion score (Equation 3) and $w_i^{\text{ent}} = f(H_i)$ is a function of the local entropy H_i at position i , estimated via a single forward pass of the student model. The p -value is computed via the moment-matched Gamma approximation of Equation 6, which accounts for the heterogeneous weights. Concave normalized-entropy transforms outperform linear/superlinear alternatives because they moderately upweight high-entropy positions—where the watermark has more room to influence token selection (Proposition 3)—without over-amplifying noisy extreme-entropy tokens. Unnormalized power functions ($H_i^{1.0}$, $H_i^{1.5}$) are sensitive to the absolute entropy scale and perform no better than the unweighted baseline.

F Extended Related Work

F.1 Post-Hoc Text Watermarking

Early text watermarking altered surface-level text characteristics such as characters or spacing (Bras-sil et al., 1995). Later methods modify grammatical or syntactical structures via pre-established rules (Topkara et al., 2005), including synonym substitution (Topkara et al., 2006c) and word reordering through passivization or topicalization (Topkara et al., 2006b,a; Meral et al., 2009). Text steganography follows similar principles (Winstein, 1998; Chapman et al., 2001; Bolshakov, 2004; Shirali-Shahreza and Shirali-Shahreza, 2008; Chang and Clark, 2014; Xiang et al., 2017). These edit-based systems exhibit low robustness and payload, e.g., 1–2 bits per sentence (Wilson and Ker, 2016). Deep learning methods have since been applied, including masked language models for steganography (Ueoka et al., 2021), infilling models (Yoo et al., 2023), neural lexical substitution (Qiang et al., 2023), and encoder-decoders (Abdelnabi and Fritz, 2021; Zhang et al., 2024; Xu et al., 2024).

F.2 Generation-Time LLM Watermarking

The first watermarks for machine-generated text date back to a method presumably used in Google Translate to filter translations from future training data (Venugopal et al., 2011). For LLM-generated text, two concurrent approaches appeared shortly after the release of ChatGPT: Kirchenbauer et al. (2023a) bias a subset of the vocabulary (“green-red list”), while Aaronson and Kirchner (2023) alter the sampling via the Gumbel-max trick. Both use pseudorandom seeds generated from a secret key and preceding tokens, enabling lightweight statistical detection without access to the model.

Subsequent work explores improved tests and multi-bit watermarking (Fernandez et al., 2023; Yoo et al., 2024; Qu et al., 2024), position-dependent seeds (Christ et al., 2023; Kuditipudi et al., 2023), low-entropy optimizations (Lee et al., 2023; Christ et al., 2023; Huang et al., 2023), and semantic watermarks for improved robustness (Liu et al., 2023; Liu and Bu, 2024; Fu et al., 2024; Hou et al., 2023, 2024). A key distinction is whether a method is *distortion-free*: at each generation step, the next-token distribution is preserved, i.e., $\mathbb{P}(\text{output}_t = v) = p_v^{(t)}$ for all v , where the probability is taken over the randomness of the watermark scheme (PRF seeds and, for dual-key methods, the key selection). Each individual token is drawn from the unmodified LLM distribution; only *diversity* across repeated generations for the same prompt is reduced. See subsection A.3 for detailed scheme descriptions. Green-red list methods (Kirchenbauer et al., 2023a) and low-entropy filtering methods (e.g., SWEET (Lee

et al., 2023), which skips watermarking on low-entropy tokens) are *not* distortion-free: they alter the output distribution, degrading every generation. MorphMark (Wang et al., 2025) adaptively scales the green-red bias based on the natural green-list probability mass, reducing distortion in low-entropy contexts, but remains non-distortion-free since it still applies a logit bias. Semantic watermarks (Liu et al., 2023; Liu and Bu, 2024; Hou et al., 2023) require auxiliary semantic encoders at generation time, making them harder to deploy. Gumbel-max (Aaronson and Kirchner, 2023), Permute-and-Flip (Zhao et al., 2024), DiPMark (Wu et al., 2023) (distortion-free green-red via pseudorandom permutations), SynthID-Text (Dathathri et al., 2024) (deployed in Google Gemini via tournament-based sampling), and WaterMax (Giboulot and Furon, 2024) (multiple generations per query, impractical for production) are distortion-free. Toolkits have also been introduced to benchmark these methods (Piet et al., 2023; Pan et al., 2024). Recent large-scale evaluations (Fernandez et al., 2025) show that Gumbel-max and SynthID achieve the best detectability-quality Pareto frontier among all methods, strictly dominating DiPMark, green-red variants, and semantic watermarks.

TextSeal builds on the Gumbel-max framework but introduces dual-key generation for diversity, entropy-weighted detection, and localized multi-region search—none of which are present in prior work. We therefore compare TextSeal against these two practical baselines. Because all three are distortion-free, the comparison is controlled: we fix the LLM, temperature, and top- p , and only vary the watermark-specific diversity parameter (key routing probability α for TextSeal, tournament depth for SynthID), isolating the watermark’s effect from the decoding strategy.

F.3 Post-Hoc LLM Watermarks for Data Protection

Recent works apply LLM watermarks to training or evaluation data via paraphrasing. Most exploit watermark radioactivity (Sander et al., 2024), i.e., the detectable traces left when watermarked text is used for training. Applications include detection of texts used in retrieval-augmented generation (Jovanović et al., 2025), benchmark contamination detection (Sander et al., 2025), and training data copyright (Zhang et al., 2025). Waterfall (Lau et al., 2024) evaluates post-hoc watermarking through LLM paraphrasing for provenance on code and natural text. In section 6, we demonstrate that TextSeal’s watermark transfers through distillation, extending this line of work to reasoning trace provenance.
