Abstract:

Acoustic information provides rich cues about object location, material properties, and changes caused by contact or motion. This paper introduces a new set of acoustic-aware manipulation tasks for imitation learning, in which robots must use auditory cues to determine manipulation targets. These tasks require sound source localization and identification for active exploration in robotic manipulation. Also, we propose a multimodal imitation learning framework, Spatial-Spectral Audio Action (S2A2), that integrates visual features with acoustic spatial and acoustic signal information for the acoustic-aware manipulation tasks. We implemented S2A2 models that integrates policies such as ACT, Diffusion Policy, VQ-BeT, and π_0 , into our framework. Simulation experiments showed that the proposed method is the most effective for tasks requiring both position and timbre. Furthermore, real-robot experiments confirm the applicability of the proposed tasks and framework to real-world manipulation.

Keywords: Multimodal Imitation Learning, Robot Manipulation, Robot Audition, Sound Source Localization

1 Introduction

Imitation learning, which acquires manipulation policies from human demonstrations, has been widely studied as a framework for robots to acquire complex manipulation skills [1, 2, 3]. Recent advances in deep learning have enabled policy learning that directly predicts high-dimensional, continuous actions from image observations and robot states, with applications to diverse robotic manipulation tasks such as object manipulation, contact-rich tasks, and bimanual operation [4].

However, most existing imitation learning tasks implicitly assume that the manipulation target is visually observable and that the goal can be visually associated. This assumption can break down under lighting variation, occlusion, the presence of multiple objects with identical or similar appearance, or when an object’s internal state or events do not appear in images [5]. To mitigate such partial observability, research integrating modalities such as touch and sound in addition to vision has been pursued [6, 7, 8, 9, 10, 11].

In this work, we focus on acoustic information, which contains diverse cues that do not appear in object appearance. Contact and collision sounds reflect object material and contact state [6, 12, 13, 14, 15], and sounds accompanying interactions such as pouring, shaking, and flowing provide cues for estimating the amount or flow rate of granular materials [16, 17] and liquid height [18, 19]. Furthermore, through active exploration such as shaking, tapping, and rubbing objects, a robot can elicit acoustic cues unavailable from vision alone [20, 21, 22]. Importantly, acoustic information

can carry not only signal information (what is happening) but also spatial information (where it is happening).

This property gives rise to task settings that differ from conventional vision-centric manipulation. For example, when selecting a sound-emitting object among visually identical objects, determining object state or destination from timbre, or deciding the next action from acoustic cues obtained by shaking an object, the policy must integrate acoustic spatial and acoustic signal information, in addition to visual object layout, to generate actions. We introduce such tasks, in which a spatially distributed sound environment directly governs target selection, goal determination, or active exploration, as *acoustic-aware manipulation tasks*.

Existing acoustic robotic manipulation research has mainly used spectrograms from contact or single microphones to identify timbre, contact events, and object state [5, 6, 14, 13, 23]. Robot audition, centered on sound source localization, tracking, and separation with microphone arrays, has targeted dialogue, navigation, and source tracking, but its integration into manipulation policies has been limited [24, 25].

We therefore propose the Spatial-Spectral Audio Action (S2A2) framework, which integrates an acoustic spatial map representing acoustic spatial information and a spectrogram representing acoustic signal information with visual information. Specifically, we combine an acoustic spatial map corresponding to the likelihood of source position based on the MUSIC method [26, 27] with a spectrogram extracted by Spotforming [28] that emphasizes the acoustic signal information at that position, so that the policy can use where and how a sound is produced.

We apply S2A2 to the acoustic-aware manipulation tasks and evaluate it using a manipulator robot and multiple microphone arrays in both simulation and the real world, verifying that spatial acoustic representations function effectively in real manipulation.

Our contributions are threefold:

- We introduce acoustic-aware manipulation tasks in which a spatially distributed sound environment is involved in target selection, goal determination, and active exploration.
- We propose S2A2, a multimodal imitation learning framework integrating acoustic spatial and acoustic signal information with vision.
- We systematically evaluate the contribution of acoustic information to policy learning through the acoustic-aware manipulation tasks, in both simulation and real-world environments.

2 Related Work

2.1 Imitation Learning and Multimodal Manipulation

Most recent imitation learning methods for robot manipulation rely primarily on visual observations [29]. Vision-Language-Action models such as RT-2 [30] and OpenVLA [31] further connect vision- and language-based task specifications to action generation for general manipulation policies [4]. However, when manipulation-relevant information is not visible from appearance, or when objects are visually indistinguishable, vision and language alone cannot sufficiently resolve physical ambiguity.

To address this limitation, non-visual sensor modalities have been integrated into imitation learning. In particular, touch captures post-contact mechanical states and local object properties, and visuo-tactile policies have been shown to outperform vision-only policies in dense packing [6], contact-rich manipulation [7, 8, 9, 10], and in-hand manipulation [11]. The acoustic representations studied in this work are complementary to touch and language, suggesting the potential for broader multimodal manipulation when combined with these modalities.

Figure 1: Overview of the S2A2 framework.

2.2 Manipulation with Acoustic Modality

The acoustic modality has been used in many perception tasks, including material identification [20, 32], estimation of granular material flow rate and amount [16, 17], and liquid height estimation [18, 19]. For robotic manipulation, policy learning [6, 14] and action generation [12] using contact sounds have been proposed, and pretraining on large-scale acoustic datasets [13] and integration with VLAs [23] have been studied.

Beyond contact sounds, The Sound of Simulation [15] addresses sim-to-real policy learning with generative acoustic data augmentation, and CAVER [21] and MOSAIC [22] address the integration of active exploration and acoustic information. Play it by Ear [5] combines vision and sound for manipulation under occlusion. However, most existing work uses single-channel sound from near the gripper or from contact microphones, and the use of microphone arrays to capture the sound environment spatially is limited.

2.3 Robot Audition and Microphone Array Processing

Robot audition has studied sound source localization, tracking, and separation using microphone arrays under the environmental noise in which robots operate [24, 25]. Related work using multiple microphone arrays includes calibration with asynchronous arrays [33], acoustic scene reproduction in virtual space [34], and source tracking [35]. In particular, Spotforming [28], which combines multiple arrays with NMF, emphasizes sources in a target region and suppresses ambient and co-directional noise. This work can be positioned as the first to connect these robot audition techniques to manipulation imitation learning.

3 Spatial-Spectral Audio Action (S2A2) framework

As shown in Fig. 1, the S2A2 framework consists of an environment setup, the S2A2 model, and the acoustic-aware manipulation tasks. The S2A2 model consists of processing pipelines that extract per-modality features from observations and a multimodal policy that integrates them to output the next action.

3.1 Problem Formulation

The S2A2 framework targets acoustic-aware manipulation tasks in which the manipulation target or destination cannot be uniquely determined from vision alone, and determines actions using acoustic spatial and acoustic signal information in addition to vision.

We formulate this as an imitation learning problem conditioned on visual and auditory observations. Each observation o_t consists of an RGB image $\mathbf{I}_t$, multi-channel acoustic information A_t , and proprioception s_t ; from A_t we obtain an acoustic spatial map S_t and a spectrogram G_t . Based on these observations, the S2A2 model learns a policy π_θ that predicts an action sequence $a_{t:t+H-1}$ up to H steps ahead. Training minimizes the imitation learning loss measuring the deviation between predicted and expert actions over a dataset $\mathcal{D}$ of expert trajectories:

$$\min_{\theta} \mathbb{E}_{(o_t, a_{t:t+H-1}) \sim \mathcal{D}} [\mathcal{L}_{\text{BC}}(\pi_\theta(o_t), a_{t:t+H-1})]. \quad (1)$$

The specific loss depends on the policy network; details are given in Section 3.4 and Appendix A.1.

3.2 Acoustic-Aware Manipulation Tasks

To evaluate the role of acoustic information in manipulation decisions, we use four manipulation tasks, termed acoustic-aware manipulation tasks. Table 1 summarizes them. In every task, the environment contains target objects and destination boxes, and the manipulator must grasp the appropriate object and drop it into the specified box. Object initial positions are randomized, while box positions are fixed.

The **Localization task** uses two visually indistinguishable objects, only one of which continuously emits sound; the manipulator grasps the sounding object and places it in the box. A single sound is used across all episodes, so the information needed to select the grasp target is the spatial position of the source.

The **Identification task** uses one object and two boxes. The object continuously emits one of two sounds, and the manipulator transports it to the box corresponding to that sound. The box position for each sound is fixed across episodes. Since there is a single sounding object, the grasp target is uniquely determined from vision and acoustic spatial information is unnecessary; sound identification is required to select the correct destination.

The **Localization & Identification task (L&I Task)** uses two visually indistinguishable objects and two boxes. Only one object continuously emits sound, which is one of two sounds. The manipulator identifies the grasp target from acoustic spatial information and transports it to the corresponding box based on the sound. The box position for each sound is fixed across episodes. Thus, this task requires source localization for target selection and sound identification for destination selection.

The **Exploratory task** uses two visually indistinguishable objects and one box. Neither object emits sound at rest, and only one emits sound when moved. The manipulator must grasp and shake each object in turn to check for sound and place the sounding object in the box.

3.3 Processing Pipeline

The S2A2 model has three pipelines that process acoustic spatial information, acoustic signal information, and visual information. Each pipeline consists of preprocessing and an encoder appropriate to its input modality. Except for the RGB image pipeline, which directly uses the vision encoder of the underlying policy, this section describes the acoustic spatial map pipeline and the spectrogram pipeline.

Table 1: Acoustic capabilities relevant to each task in the acoustic-aware manipulation tasks.

Task	Space	Signal	Explore
Localization	✓	–	–
Identification	–	✓	–
L&I	✓	✓	–
Exploratory	✓	✓	✓

3.3.1 Acoustic Spatial Map Pipeline

As shown in Fig. 2, all microphone arrays are placed on the same plane as the workspace. The acoustic spatial map pipeline estimates the likelihood of source direction from the multi-channel acoustic information recorded by the arrays and projects it onto a 2D map corresponding to the workspace. Specifically, the multiple signal classification (MUSIC) method [26] is applied to the multi-channel signal of each array. Input audio is acquired at a 16 kHz sampling rate and transformed to the frequency domain by a short-time Fourier transform (STFT) with an FFT length of 512 and 50% overlap.

The log-normalized spatial spectrum per direction is used as the direction-of-arrival (DOA) score. With an attenuation term based on distance from the array center, it is projected onto a 224×224 2D plane corresponding to the array plane of the workspace, yielding the acoustic spatial map $S \in \mathbb{R}^{224 \times 224 \times N}$, where N is the number of arrays. Details are in Appendix D. The acoustic spatial map S is fed to a spatial encoder to produce features usable by the policy network. The spatial encoder is a ResNet-18 with the input channel count extended to N , trained from scratch, and outputs a feature map.

3.3.2 Spectrogram Pipeline

The spectrogram pipeline extracts the acoustic signal information of the target source. From the acoustic spatial map S , the source presence likelihood is computed, and peak extraction selects source candidates. Since only one source is present at a time, the highest peak is taken as the candidate. Source separation by Spotforming [28] is applied to the candidate to generate the spectrogram. Details are in Appendix D. The spectrogram is fed to a spectral encoder, a ResNet-18 with a single input channel trained from scratch, to produce features usable by the policy network.

3.4 Multimodal Policy

The multimodal policy integrates the per-modality features from the processing pipelines with proprioception to generate robot actions. We adopt four policy networks for action generation: ACT [36], Diffusion Policy [37], VQ-BeT [38], and π_0 [39].

As described in Section 3.3, each pipeline outputs a feature map. The format for feeding these feature maps to the policy network differs by policy architecture; details are in Appendix A.1.

4 Experiments

4.1 Simulation Experiments

We first conduct simulation experiments to examine the relationship between the processing pipelines in the S2A2 framework and the acoustic-aware manipulation tasks defined in Section 3.2. We compare four conditions by varying the combination of processing pipelines: (**Baseline**) uses only the RGB image pipeline, with no acoustic information; (**S2A2**) the standard proposed method using all three pipelines; (**w/o Spec.**) removes the spectrogram pipeline, using visual information and acoustic spatial information from the acoustic spatial map; (**w/o Spat.**) removes the acoustic spatial map pipeline, using visual information and acoustic signal information from the spectrogram. In all conditions, the multimodal policy structure is identical, concatenating the features output by each pipeline and feeding them to the policy network. As shown in Fig. 2, we build a simulation environment integrating the physics simulator Genesis [40] and the acoustic simulator Pyroomacoustics [41] (details in Appendix H). Other optimization settings and internal model parameters are summarized in Appendix A. Each task is trained with three random seeds, and the evaluation metric is the fraction of 100 trials in which the correct object is grasped and placed in the correct box within about 23 seconds (700 steps).

Figure 2: Simulation settings. A simulation environment integrating the physics simulator Genesis and the acoustic simulator Pyroomacoustics. RGB images are updated at 30 FPS and acoustic information from the microphone arrays at 10 FPS. The workspace center is 500 mm in front of the Franka Emika Panda, with four microphone arrays placed at equal intervals on a circle of radius 300 mm around it. Two cameras (side and front) are set to view the workspace center.

Figure 3: Task success rate versus training steps. Training curves of the four policies (ACT, Diffusion Policy, VQ-BeT, π_0) of the S2A2 model on the four tasks. The localization and identification tasks were evaluated every 10,000 steps up to 100,000 steps; the L&I and exploratory tasks every 20,000 steps up to 200,000 steps.

4.1.1 Task Success Rate Comparison

Table 2 shows success rates across the four tasks, and Fig. 3 shows their progression over training steps. Across all tasks, the best success rate is consistently obtained by the model matching the task’s required condition. In the localization task, which requires only acoustic spatial information, and the identification task, which requires only acoustic signal information, the models with only the corresponding condition (w/o Spec. and w/o Spat.) match the S2A2 model; in the L&I task, which requires both, only the S2A2 model with both pipelines achieves a relatively high success rate.

The S2A2 model is particularly effective in the L&I task, which requires both spatial and signal information. Adding a processing pipeline unnecessary for the task can degrade performance, suggesting that under limited data, redundant acoustic input may hinder policy learning. The improvement from acoustic information depends on the policy: ACT and Diffusion Policy show marked improvement, VQ-BeT shows a small improvement, and π_0 varies widely across tasks (Appendix G).

4.1.2 Latent Feature Visualization

We visualize the intermediate-layer latent features of ACT and Diffusion Policy in Fig. 4, projected to 2D by t-SNE [42], and discuss their relation to task success rate. The visualization method and results for all policies are summarized in Appendix B.

Fig. 4(a) shows the latent space of Diffusion Policy on the L&I task. The relatively high success rate of the S2A2 model is also reflected in the latent space. In the S2A2 model, both the sound type and the sound coordinate (the Y coordinate of the target position) are relatively well separated and

Table 2: Comparison of task success rates (%) across all tasks (Mean $\pm$ STD). The best value within each policy is shown in bold.

Model	Policy	localization task	identification task	L&I Task	exploratory task
Baseline	ACT	20.3 $\pm$ 7.2	39.3 $\pm$ 4.0	11.0 $\pm$ 3.5	35.0 $\pm$ 5.3
	Diffusion Policy	13.3 $\pm$ 1.2	41.3 $\pm$ 2.5	9.3 $\pm$ 6.1	26.3 $\pm$ 0.6
	VQ-BeT	12.7 $\pm$ 6.8	24.0 $\pm$ 6.9	7.7 $\pm$ 1.2	17.3 $\pm$ 5.8

	Diffusion Policy	15.3 $\pm$ 1.2	80.3 $\pm$ 3.8	8.7 $\pm$ 3.8	6.3 $\pm$ 2.3
	VQ-BeT	12.3 $\pm$ 3.8	49.3 $\pm$ 9.8	19.0 $\pm$ 1.0	25.0 $\pm$ 3.6
	π_0	14.7 $\pm$ 5.7	78.7 $\pm$ 6.0	19.7 $\pm$ 3.8	9.3 $\pm$ 10.4

Figure 4: Latent space visualization. (a) Comparison for Diffusion Policy on the L&I task. The top row is colored by the sound type, and the bottom row encodes the Y coordinate of the sounding object as a colormap. In the top row, sound A is orange and sound B is blue. (b) Intermediate-layer latent representations of ACT and Diffusion Policy on the exploratory task, separated by t-SNE, with the Y coordinate of the sounding grasp target encoded as a colormap. Results for all policies are in Appendix B.

structured, whereas in models lacking the corresponding information the separation is weaker. Both quantitative and qualitative evaluations therefore support that acoustic spatial and acoustic signal information play independent roles in the latent space.

Fig. 4(b) shows the latent space of Diffusion Policy and ACT on the exploratory task. ACT’s latent space forms a clear structure corresponding to source position, whereas Diffusion Policy’s is less structured. This difference in latent structuring can be interpreted as the source of the performance difference on the exploratory task.

4.2 Real-Robot Experiments

To verify the simulation findings in the real world, we use only the right arm of ILOHA, an open-source ALOHA-type [36] bimanual manipulator. The six joints and the 1-DoF gripper are treated

Figure 5: Real-robot examples. (a) Top: the robot during the exploratory task. Middle: the acoustic spatial map summed over channels, shown as a colormap overlaid on the top-down camera image. Bottom: the visualized spectrogram. (b) Task success rates over 100 trials for the baseline and S2A2 on the L&I and exploratory tasks in the real-robot experiments.

as state and action, so both are 7-dimensional. Visual information is obtained from a top-down view and a RealSense camera mounted on the end-effector, cropped and resized to 224×224 RGB images. Acoustic information is acquired with four circular microphone arrays (TAMAGO-03), each with 8 microphones on a circle of radius 35 mm, at a 16 kHz sampling rate. The arrays are placed at the vertices of a rectangle (0.6 m by 1.2 m, top-down) surrounding the workspace.

We select two tasks for evaluation: the L&I task, which requires the capabilities of both the localization and identification tasks, and the exploratory task, which requires active exploration. Their success rates are shown in Fig. 5(b). This confirms that, for tasks difficult to solve with the vision-only baseline, the S2A2 model integrating acoustic information is also effective in the real world.

5 Conclusion

We introduced acoustic-aware manipulation tasks, in which the manipulation target or destination cannot be uniquely determined from vision alone, and proposed S2A2, an imitation learning framework that uses acoustic information. Simulation experiments showed the importance of using representations matched to the acoustic capabilities a task requires, that unnecessary acoustic modalities can degrade performance, and that the efficiency of using acoustic information depends on the policy architecture. Real-robot experiments further confirmed the effectiveness of S2A2, which outperformed the vision-only baseline.

6 Limitations

First, we focused on demonstrating the effectiveness of integrating spatial and signal auditory information into imitation learning for tasks that require acoustic capabilities, so real-robot validation was conducted on a single robot in a limited environment. Generalization to diverse platforms including bimanual and mobile robots, to diverse environmental conditions, and especially to environments with many simultaneous sound sources is left for future work. Second, the efficiency of using acoustic information depends on the policy architecture, with limited improvement under some conditions for π_0 and VQ-BeT. Designing effective integration of acoustic information into large-scale pretrained models and incorporating sim-to-real methods [15] are important future directions.

Acknowledgments

If a paper is accepted, the final camera-ready version will (and probably should) include acknowledgments. All acknowledgments go at the end of the paper, including thanks to reviewers who gave useful comments, to colleagues who contributed to the ideas, and to funding agencies and corporate sponsors that provided financial support.

A Implementation Details

This appendix describes the implementation details of the S2A2 model. Specifically, Section A.1 provides the details of the policy network architectures and hyperparameters, Section A.2 provides the details of the audio processing, and Section A.3 describes the changes introduced to the S2A2 model configuration for the real-robot experiments relative to simulation.

A.1 Policy Architecture and Hyperparameters

This section describes, for the four policy networks evaluated in this work, the feature extraction from observations, the action generation, and the training and inference procedures. S2A2 denotes the standard model that uses image information, the acoustic spatial map, the spectrogram, and proprioception. w/o Spat. denotes the model without the acoustic spatial map pipeline, and w/o Spec. denotes the model without the spectrogram pipeline.

A.1.1 ACT

The ACT vision encoder uses ResNet-18, initialized with weights pretrained on ImageNet. The encoders for the acoustic spatial map and the spectrogram use the ResNet-18 architecture with only the number of input channels modified, and are trained from scratch without pretraining. The feature maps output by the RGB image, acoustic spatial map, and spectrogram encoders are mapped to a sequence of 512-dimensional tokens by a 1×1 convolution. After adding positional embeddings to these tokens and appending the proprioception as a state token, the tokens are fed into a transformer composed of an encoder and a decoder. Within ACT, a VAE maps action sequences into a latent space. In this configuration, the transformer has a hidden dimension of 512, 8 attention heads, 4 encoder layers, and 1 decoder layer, and the VAE latent dimension is 32. The decoder outputs an action chunk of length H_{act} . During training, the VAE is used jointly and the loss function in Eq. (2) is minimized.

$$\mathcal{L}_{\text{ACT}} = \frac{1}{H_{\text{act}} d_a} \sum_{h=0}^{H_{\text{act}}-1} m_h \|\hat{a}_{t+h} - a_{t+h}\|_1 + \beta_{\text{KL}} D_{\text{KL}}(q_\phi(z \mid a_{t:t+H_{\text{act}}-1}, s_t) \parallel \mathcal{N}(0, \mathbf{I})) \quad (2)$$

Here, d_a is the action dimensionality, h is the time index within the action chunk, and $\hat{a}_{t+h}$ and a_{t+h} are the predicted action and the expert action, respectively. $m_h \in \{0, 1\}$ is a mask that excludes the padding at the sequence ends from the loss computation, s_t is the proprioception, z is the VAE latent variable, ϕ denotes the parameters of the VAE encoder, and q_ϕ denotes the resulting latent distribution. $\mathcal{N}(0, \mathbf{I})$ is the standard normal distribution with zero mean and identity covariance, D_{KL} is the Kullback–Leibler divergence, and the weight of this term is set to $\beta_{\text{KL}} = 10$.

A.1.2 Diffusion Policy

In Diffusion Policy, the vision encoder that processes the visual information is a Residual Network with 18 layers (ResNet-18). No pretrained weights are used; all parameters are randomly initialized. Input images are resized to 84×84 pixels before being fed to the encoder. The encoders that process the acoustic spatial map and the spectrogram (a time–frequency representation) used as acoustic information are ResNet-18 with only the number of input channels modified, and likewise use no pretrained weights. The feature map output by each encoder is linearly projected onto a two-dimensional feature map with $n_{\text{key}} = 32$ keypoint features. A spatial softmax is then applied to each channel. The spatial softmax normalizes each location on the feature map into a probability distribution. Based on the resulting weights, a weighted average of the normalized image coordinates is computed, extracting the keypoint feature (the representative location of the feature) corresponding to each channel. The extracted keypoint features are flattened into a one-dimensional vector and concatenated with the proprioception, which represents the robot’s internal state such as joint angles and joint velocities. This vector is used as the global conditioning vector provided to the U-Net. The channel counts of the U-Net used as the noise prediction model in Diffusion Policy are (512, 1024, 2048). During training, for an action sequence $x_0 = a_{t-1:t+14}$ of length $H_d = 16$,

at a step k sampled uniformly from the 100 diffusion steps of the Denoising Diffusion Probabilistic Model (DDPM), the noised x_k obtained by adding noise $\epsilon \sim \mathcal{N}(0, \mathbf{I})$ is generated according to Eq. (3).

$$x_k = \sqrt{\bar{\alpha}_k}x_0 + \sqrt{1 - \bar{\alpha}_k}\epsilon \quad (3)$$

Here, $\bar{\alpha}_k$ is a coefficient determined by the DDPM noise schedule. In this work, we use `squaredcos_cap_v2` as the noise scheduler. Let the U-Net model be ϵ_θ and let the vector encoding the observation conditioning be $g(o)$. We adopt `epsilon` as the prediction type and train the U-Net to directly estimate the noise ϵ added during the diffusion process, using the following loss function.

$$\mathcal{L}_{\text{Diff}} = \mathbb{E}_{x_0, \epsilon, k} \left[\frac{1}{H_d d_a} \|\epsilon_\theta(x_k, k, g(o)) - \epsilon\|_2^2 \right] \quad (4)$$

Here, θ denotes the learnable parameters of the U-Net and o denotes the observation. At inference time, 100 reverse-diffusion steps are performed, and 8 steps of actions starting from the last time step of the observation history are output as execution candidates. The samples are clipped to $[-1, 1]$.

A.1.3 VQ-BeT

In VQ-BeT, the encoder that processes the visual information uses the same configuration as in Diffusion Policy: input images are resized to 84×84 pixels before being fed to the encoder, and a spatial softmax is applied to the feature map output by each encoder to extract keypoint features, as in Diffusion Policy. The extracted features from each pipeline, the proprioception representing the robot’s internal state such as joint angles and joint velocities, and the Action Query Tokens are fed to the policy network. An Action Query Token is a learnable query vector for predicting future action sequences, with each token responsible for generating one action chunk. The policy network is a decoder-only transformer (GPT) with a hidden dimension of 512, 8 attention heads, and 8 transformer layers. We represent the action output using a Residual Quantized Variational Autoencoder (RQ-VAE) [43]. RQ-VAE quantizes a continuous-valued action sequence into multiple stages of discrete codes. In this work, an action chunk of length 5 is converted into a two-level sequence of discrete codes. The codebook (the dictionary of discrete representations) at each level has a size of 16. The RQ-VAE is trained for 20,000 steps independently of the policy network, after which the obtained codebook is fixed and used. During training, the policy network is trained against the fixed RQ-VAE. Each Action Query Token predicts the probability distribution over the discrete codes at each level and a continuous offset for correcting the quantized action representation. The discrete codes are intended to represent the coarse action of the action chunk, while the continuous offset corrects the quantization error. Let the predicted action chunk be $\hat{A}_j$, the ground-truth action chunk be A_j , the ground-truth codes at the first and second levels be $c_j^{(1)}$ and $c_j^{(2)}$, respectively, and the corresponding predicted code distributions be $p_{\theta,j}^{(1)}$ and $p_{\theta,j}^{(2)}$. The loss function is then defined by the following equation.

$$\mathcal{L}_{\text{VQ}} = \frac{1}{J} \sum_{j=1}^J \left[\lambda_{\text{off}} \frac{1}{H_q d_a} \|\hat{A}_j - A_j\|_1 + \lambda_1 \text{FL}(p_{\theta,j}^{(1)}, c_j^{(1)}) + \lambda_2 \text{FL}(p_{\theta,j}^{(2)}, c_j^{(2)}) \right] \quad (5)$$

Here, θ denotes the learnable parameters of the policy network, j is the index of the Action Query Token, $J = 3$ is the total number of Action Query Tokens, $H_q = 5$ is the action chunk length handled by one token, and d_a is the dimensionality of the action space. λ_{off} , λ_1 , and λ_2 are weighting coefficients that balance the contributions of the reconstruction loss for the continuous offset, the first-level discrete code prediction loss, and the second-level discrete code prediction loss, respectively. In this work, we set $\lambda_{\text{off}} = 10000$, $\lambda_1 = 5.0$, and $\lambda_2 = 0.5$. In addition, FL denotes the Focal Loss, a loss function that suppresses the contribution of easily classified samples and places greater emphasis on samples prone to misclassification. Letting p_c be the predicted probability corresponding to the ground-truth code c , it is defined by the following equation.

$$\text{FL}(p, c) = -(1 - p_c)^2 \log p_c \quad (6)$$

At inference time, the discrete code at each level is sampled from the predicted probability distribution, with a code sampling temperature of 0.1. The temperature controls the sharpness of the

probability distribution, with smaller values making high-probability codes more likely to be selected. The sampled discrete codes are decoded into continuous values by the RQ-VAE decoder, and the predicted continuous offset is added to produce the final action output.

A.1.4 π_0

The original π_0 is a policy network that takes images and language as its primary inputs. In this work, we use SigLIP (Sigmoid Loss for Language–Image Pre-training) as the vision encoder that processes images. In addition, the encoders for the acoustic spatial map and the spectrogram that process the acoustic information are ResNet-18 with a modified number of input channels. These encoders use no pretrained weights and are randomly initialized. The feature map output by each acoustic encoder is projected onto the hidden dimension of PaliGemma by a 1×1 convolution and then converted into a token sequence. The resulting acoustic tokens are concatenated with the output tokens of the vision encoder and placed on the prefix side of the input text token sequence. The proprioception representing the robot’s internal state such as joint angles and joint velocities, the noised action sequence, and the timestep embedding are placed on the suffix side. The model architecture combines PaliGemma (Gemma-2B) with an Action Expert (Gemma-300M) for action generation, and the model weights are initialized from `1erobot/pi0_base`. The state and action vectors are zero-padded to 32 dimensions. This unifies the input format with the fixed-dimensional representation expected by PaliGemma and the Action Expert. In this method, the model is trained based on Flow Matching. Flow Matching is a generative model that directly learns a velocity field along a continuous path between the data distribution and a simple noise distribution. Instead of learning a sequential denoising process as in diffusion models, it is trained to predict the ideal velocity vector at each time. Let the ground-truth action sequence be a , the standard normal noise of the same shape be ϵ , and the Flow Matching time be $r \in [0, 1]$. The target velocity u_r used as the training objective is defined by the following equation.

$$x_r = r\epsilon + (1 - r)a, \quad u_r = \epsilon - a \quad (7)$$

Here, x_r is the intermediate state obtained by linearly interpolating between the ground-truth action sequence and the noise, and u_r is the ideal velocity vector pointing from that state toward the noise distribution. Following π_0 [39], to prevent r from taking exactly 0 or 1, we add a small offset and use $r = 0.999b + 0.001$, where b is sampled from the Beta distribution $\text{Beta}(1.5, 1.0)$. Letting the velocity-field model be v_θ , we minimize the following loss function so that the model predicts the target velocity u_r .

$$\mathcal{L}_{\pi_0} = \mathbb{E}_{a, \epsilon, r} \left[\frac{1}{H_\pi d_a} \|v_\theta(x_r, r, o) - u_r\|_2^2 \right] \quad (8)$$

Here, θ denotes the learnable parameters of the velocity-field model, $H_\pi = 50$ is the action chunk length, x_r is the noised action, u_r is the target velocity from the ground-truth action toward the noise distribution, and o is the observation conditioning, which includes the prefix and the proprioception. At inference time, the action sequence is generated by initializing the trajectory from standard normal noise and numerically integrating the ordinary differential equation (ODE) defined by Flow Matching backward from $r = 1$ to $r = 0$ using the learned velocity field. In this work, the ODE integration is performed in 10 steps, and the resulting action sequence is output as the execution candidate. During training, gradient checkpointing is enabled to reduce memory usage, and gradient clipping is applied with a maximum gradient norm of 1.0 to stabilize training.

A.1.5 Hyperparameters in Policy Network Training

Table 3 lists the main training hyperparameters for each policy network. The number of training steps is generally 100,000 steps; for the exploratory task and the L&I task experiments, it is set to 200,000 steps to accommodate these more complex tasks.

A.2 Hyperparameters for Audio Processing

Table 4 lists the audio processing parameters used in simulation. Under the default condition, four microphone arrays are used, and the simulation runs at 30 FPS while the acoustic representation

Table 3: Training hyperparameters for each policy network. ‘—’ indicates not applicable.

Item	ACT	Diffusion Policy	VQ-BeT	π_0
Optimizer	AdamW	Adam	Adam	AdamW

Table 4: Audio processing parameters used in simulation.

Item	Value
Sampling rate	16 kHz
STFT FFT length	512
STFT overlap	50%
Audio window	1.0 s
Audio update rate	10 Hz
Number of arrays n	4
Microphones per array	8
Microphone array radius	3.5 cm
Array placement radius	30 cm
Room size	10 m $\times$ 10 m $\times$ 3 m
Reflection order	3
MUSIC source number	3
NMF components	50
NMF threshold	1.6×10^{-3}
NMF iterations (initial)	40
NMF iterations (warm start)	15
NMF tolerance	2.0×10^{-2}
NMF beta divergence	2
NMF max mask ratio	0.2
Peak selection	local maximum
Number of peaks	1
DAS beamforming normalization	by mic count
Spectrogram frequency range	0–8000 Hz
Spectrogram normalization	min–max
Distance attenuation d_{floor}	10.0 m
Distance attenuation γ	1.0

is updated every three frames, yielding an update rate of 10 Hz. Both the acoustic spatial map and the spectrogram are resized to 224×224 pixels before being fed to the policy network. The NMF in Spotforming is iterated for 40 steps only at the first time step; at subsequent time steps it is terminated after 15 steps using a warm start.

A.3 Differences between Simulation and Real-World Experiments

In the real-robot experiments, the same pipelines as in simulation are used for the acoustic spatial map and the spectrogram. However, to account for the microphone placement, the robot configuration, and the noise characteristics present in real recordings, we introduced the following differences.

Robot and camera inputs. In simulation, we target the Franka Panda and use a 9-dimensional state and a 9-dimensional position control command. The camera inputs are the front and side RGB images rendered in Genesis and saved at 224×224 pixels. In contrast, the real-robot experiments use a 7-dimensional state and action comprising the six joints of the right arm of ILOHA and the gripper opening, and feed RGB images obtained from a top-down view and a RealSense camera mounted on the end-effector to the policy network. Specifically, a 1280×720 pixel image is acquired from the top-down RealSense, and a 640×480 pixel region at the lower-center of that image is cropped. This processing enlarges the workspace region of the RealSense image for use as input. A 640×480 pixel image is acquired from the end-effector RealSense. The two 640×480 pixel images obtained

from the top-down and end-effector cameras are each resized to 224×224 pixels and used as inputs to the vision pipeline.

Acoustic input and microphone placement. In simulation, Pyroomacoustics is used to model the sound sources and room reflections and to generate synthetic sound. We use four circular 8-channel arrays of radius 0.035 m, with the center of each array placed on a circle of radius 0.3 m. In the real-robot experiments, real recordings are made at 16 kHz from four circular 8-channel arrays of the same specification, with the center of each array placed at the four corners of a $1.2 \text{ m} \times 0.6 \text{ m}$ rectangle.

MUSIC and DOA normalization. The number of sound sources assumed by MUSIC is set to 3 in simulation and 1 on the real robot. For the normalization of the DOA spectrum, in simulation the MUSIC output is log-transformed and then normalized by the sum over azimuth. On the real robot, the output is converted to relative dB values, normalized using the 60th percentile as the noise floor and 15 dB as the dynamic range, and an additional normalization is applied along the frequency axis.

Acoustic spatial map and Spotforming. For the coordinate system of the acoustic spatial map, simulation uses a local grid corresponding to the workspace. The real robot uses map coordinates of 1.4 m square, matched to the rectangular microphone placement. The distance attenuation parameters are $d_{\text{floor}} = 10.0 \text{ m}$ and $\gamma = 1.0$ in simulation, whereas on the real robot they are set to $d_{\text{floor}} = 0.0 \text{ m}$ and $\gamma = 0.0$, effectively disabling the attenuation. For peak selection in Spotforming, simulation applies an exponent of 1.0 to the channel-summed acoustic spatial map and adopts local maxima, whereas the real robot uses an exponent of 4.0 and adopts the point of maximum value. For the spectrogram, simulation normalizes the 0–8000 Hz range with min–max normalization, whereas the real robot band-limits to 0–4000 Hz and normalizes using the 2nd–98th percentiles.

ACT inference settings. For ACT inference, simulation uses a temporal ensemble with a weighting coefficient of 0.01 and re-runs inference after every single executed step. The real-robot experiments do not use a temporal ensemble and continuously execute 30 steps from the action chunk obtained in a single inference.

B Additional Latent Space Visualizations

This appendix presents additional t-SNE plots for the policy–task combinations that could not be included in Fig. 4 of the main text.

B.1 Extraction of Latent States

Because each policy has a different structure, the features used as latent states also differ. For each policy, we extracted both a final-layer representation close to the action output and an intermediate-layer representation from within the policy, and visualized each with t-SNE. As the final-layer representation, for ACT we used the features immediately before the representation produced by the transformer decoder is projected onto the action sequence. For Diffusion Policy, we used the features immediately before the U-Net output is converted into the noise prediction. For VQ-BeT, we used the features immediately before the contextual representation produced by the GPT-style policy network is converted into action tokens or action values. For π_0 , we used the features immediately before the representation integrating visual, language, and state information is projected onto continuous actions.

As the intermediate-layer representation, for ACT we used the output of the transformer encoder that encodes the observation sequence. For Diffusion Policy, we used the features near the bottleneck connecting the U-Net encoder and decoder. For VQ-BeT, we used the output of the middle layer of the transformer blocks contained in the GPT-style policy network. For π_0 , we used the final

Figure 6: t-SNE visualization of ACT latent representations for the four acoustic-aware manipulation tasks. The four quadrants correspond to Localization, Identification, Exploratory, and L&I task. In each quadrant, the rows show the same embedded samples colored by different task-related variables: success/failure, sound coordinate, or sound type. The columns compare representations from the intermediate layer and the final layer. Each point denotes an observation sample from evaluation trajectories.

hidden state on the foundation-model side that integrates visual and language features. Because the same U-Net is applied multiple times during the denoising process in Diffusion Policy, we used the features obtained at the midpoint of this process as the intermediate-layer representation.

The features were recorded at each policy inference. Both the final-layer and intermediate-layer representations were averaged along the sequence axis and treated as a single latent vector per inference step. Thus, each point in the t-SNE plot corresponds to the features of an entire action sequence generated by one inference. For t-SNE, we set the output dimensionality to 2, used PCA initialization, set the learning rate automatically, and fixed all random seeds.

B.2 Additional Visualization Results by Policy

Figures 6–9 show the t-SNE plots across all tasks for ACT, Diffusion Policy, VQ-BeT, and π_0 , respectively. For each policy network of the S2A2 model, we visualize both the intermediate-layer and final-layer representations on the Localization, Identification, Localization & Identification (L&I), and Exploratory tasks. Each plot is colored by task success/failure, sound source position, and sound type as labels. For task success/failure, data points belonging to successful episodes are shown in blue, while data points belonging to failed episodes are represented with a colormap that transitions from blue at the beginning of the episode, to white in the middle, to red at the end.

Figure 7: t-SNE visualization of Diffusion Policy latent representations for the four acoustic-aware manipulation tasks. The four quadrants correspond to Localization, Identification, Exploratory, and L&I task. In each quadrant, the rows show the same embedded samples colored by different task-related variables: success/failure, sound coordinate, or sound type. The columns compare representations from the intermediate layer and the final layer. Each point denotes an observation sample from evaluation trajectories.

C Sensitivity Analysis of Audio Representation

Fig. 10 shows the sensitivity analysis results for the main hyperparameters of the proposed method. We used the S2A2 model with ACT for the evaluation.

Effect of the number of microphone arrays. Fig. 10(a) shows the success rate on the localization task as the number of microphone arrays n is varied. Since the success rate was highest at $n = 4$, we adopted this as the standard setting. When the number of arrays is small, the spatial constraints required for DOA estimation are insufficient, whereas when it is too large, the increase in redundant input channels is considered to make policy learning unstable.

Effect of the update FPS of the acoustic information. Fig. 10(b) shows the results of varying the update frequency of the acoustic spatial map and the spectrogram over the range of 1–30 FPS. Performance improved beyond 5 FPS and roughly saturated from 10 FPS onward. Based on this result, we set the standard update frequency of the acoustic information to 10 FPS.

Comparison of acoustic spatial map representations. Fig. 10(c) shows the results of varying the representation method of the acoustic spatial map. A–E in the figure denote differences in the processing applied after projecting the DOA score of each microphone array onto each position in the workspace, as described later in Appendix D. A is the same as the method described in Section 3.3.1, with no additional spatial or temporal processing. B applies spatial smoothing to the map

Figure 8: t-SNE visualization of VQ-BeT latent representations for the four acoustic-aware manipulation tasks. The four quadrants correspond to Localization, Identification, Exploratory, and L&I task. In each quadrant, the rows show the same embedded samples colored by different task-related variables: success/failure, sound coordinate, or sound type. The columns compare representations from the intermediate layer and the final layer. Each point denotes an observation sample from evaluation trajectories.

obtained in A using a Gaussian filter that averages values among neighboring pixels, suppressing local peaks and estimation noise. C takes a weighted average of the map at each time with the preceding maps, suppressing abrupt changes along the time axis. D combines the spatial smoothing of B and the temporal smoothing of C, reducing both spatial variation and temporal fluctuation. E integrates the maps obtained from multiple microphone arrays and converts them into a three-channel feature map consisting of the channel-wise mean of A, a marker indicating the position of maximum response, and a binary mask of the regions with high likelihood. As a result of the comparison, A and C showed the highest success rates; we therefore adopted A and used an acoustic spatial map in which the DOA score is directly projected onto the workspace, without additional feature imaging or smoothing.

D Detailed Implementation of the Acoustic Spatial Map Pipeline and the Spectrogram Pipeline

This appendix describes the detailed implementation of the acoustic spatial map pipeline and the spectrogram pipeline.

D.1 Acoustic Spatial Map Pipeline

The details of the processing described in Section 3.3.1 are given below. Let the number of arrays be N and the number of microphones per array be M . Let the STFT of the M -channel signal observed

Figure 9: t-SNE visualization of π_0 latent representations for the four acoustic-aware manipulation tasks. The four quadrants correspond to Localization, Identification, Exploratory, and L&I task. In each quadrant, the rows show the same embedded samples colored by different task-related variables: success/failure, sound coordinate, or sound type. The columns compare representations from the intermediate layer and the final layer. Each point denotes an observation sample from evaluation trajectories.

at the $c \in \{1, \dots, N\}$ -th array be $\mathbf{x}_{c,f,\tau} \in \mathbb{C}^M$. The spatial covariance matrix at frequency bin f is then given by Eq. (9).

$$\mathbf{R}_{c,f} = \frac{1}{T} \sum_{\tau=1}^T \mathbf{x}_{c,f,\tau} \mathbf{x}_{c,f,\tau}^H \quad (9)$$

Here, $\mathbb{C}^M$ is the M -dimensional complex vector space, $\mathbf{R}_{c,f}$ is the spatial covariance matrix at the f -th frequency bin of the c -th array, T is the number of STFT time frames, and H denotes the conjugate transpose. The MUSIC method obtains the noise subspace $\mathbf{E}_{n,c,f}$ from the eigenvalue decomposition of $\mathbf{R}_{c,f}$ and, based on its orthogonality to the steering vector $\mathbf{a}_{c,f}(\phi)$ for direction ϕ , computes the spatial spectrum by Eq. (10).

$$P_c(\phi) = \frac{1}{|\mathcal{F}|} \sum_{f \in \mathcal{F}} \frac{1}{\mathbf{a}_{c,f}(\phi)^H \mathbf{E}_{n,c,f} \mathbf{E}_{n,c,f}^H \mathbf{a}_{c,f}(\phi)} \quad (10)$$

Here, $\mathbf{E}_{n,c,f}$ is the matrix whose columns are the eigenvectors spanning the noise subspace, the subscript n denotes the noise subspace, and $\mathcal{F}$ is the set of frequency bins.

The log-transformed and normalized spatial spectrum per azimuth is taken as the direction-of-arrival (DOA) score, which is projected onto a 224×224 two-dimensional plane corresponding to the plane of the workspace where the microphone arrays lie, generating an N -channel acoustic spatial map. Let the image row index be i and the column index be j , the point in the workspace corresponding to the image coordinate $u = (i, j)$ be $p(u)$, and the array center be m_c . The value of each channel is

Figure 10: Sensitivity analysis of the audio representation. (a) Effect of the number of microphone arrays. (b) Effect of the update FPS of the acoustic information. (c) Comparison of representation methods for the acoustic spatial map.

then computed by Eq. (11).

$$S_c(u) = \frac{\bar{P}_c(\psi(p(u), m_c))}{(\|p(u) - m_c\|_2 + d_{\text{floor}})^\gamma} \quad (11)$$

Here, $\bar{P}_c$ is the normalized DOA score, $\psi(p(u), m_c)$ is the azimuth angle from m_c toward $p(u)$, $\|\cdot\|_2$ is the Euclidean distance, and d_{floor} and γ are parameters that stabilize the distance attenuation. Since the DOA score depends only on the azimuth, the same value is assigned to all points along the same azimuth. To suppress values far from the workspace, we introduced an attenuation term that depends on the distance from the array center.

D.2 Spectrogram Pipeline

In this work, we generate a spectrogram with suppressed noise and sidelobes based on Spotforming [28]. First, the integrated map over all arrays is computed as $S_{\text{sum}}(u) = \sum_{c=1}^N S_c(u)$. After applying a Gaussian filter to S_{sum} , peak extraction is performed to select source candidates. Let the azimuth of the source candidate as seen from each array be $\hat{\theta}_c$. At each array, delay-and-sum beamforming is performed according to $\hat{\theta}_c$ to compensate for the time-of-arrival differences of the sound.

$$y_c(t) = \frac{1}{M} \sum_{m=1}^M x_{c,m}(t - \tau_{c,m}(\hat{\theta}_c)). \quad (12)$$

Here, t is time, $x_{c,m}(t)$ is the signal of the m -th microphone of the c -th array, and $\tau_{c,m}(\hat{\theta}_c)$ is the relative delay for sound arriving from azimuth $\hat{\theta}_c$ to reach each microphone. Next, we construct a nonnegative matrix $\mathbf{V} \in \mathbb{R}_{\geq 0}^{F_b \times N T_b}$ by concatenating the amplitude spectrograms of the beamforming output y_c of each array along the time axis. Here, F_b is the number of frequency bins and T_b is the number of time frames per array. We decompose $\mathbf{V}$ with 50-component NMF as in Eq. (13).

$$\mathbf{V} \approx \mathbf{W}\mathbf{H}, \quad \mathbf{W} \geq 0, \mathbf{H} \geq 0 \quad (13)$$

Here, $\mathbb{R}_{\geq 0}$ is the set of nonnegative reals, $\mathbf{W} \in \mathbb{R}_{\geq 0}^{F_b \times R}$ is the basis matrix, $\mathbf{H} \in \mathbb{R}_{\geq 0}^{R \times N T_b}$ is the activation matrix, and $R = 50$ is the number of NMF components. Let $\mathbf{H}^{(c)} \in \mathbb{R}_{\geq 0}^{R \times T_b}$ be the activation matrix split into the time interval of each array. We estimate the components that are commonly strong across all arrays by Eq. (14).

$$\mathbf{Z} = \min_c \mathbf{H}^{(c)} \quad (14)$$

Here, $\min_c$ is the operation that takes the minimum over arrays for each NMF component and each time. Let $\tilde{\mathbf{Z}}$ be the matrix obtained by normalizing $\mathbf{Z}$ by its maximum value, and construct a binary mask $\mathbf{B}$ with threshold $\delta = 1.6 \times 10^{-3}$ as in Eq. (15).

$$\mathbf{B}_{r,\tau} = \begin{cases} 1 & \tilde{\mathbf{Z}}_{r,\tau} > \delta, \\ 0 & \text{otherwise} \end{cases} \quad (15)$$

Here, r is the index of the NMF component, τ is the index of the time frame in the NMF activation matrix, and $\mathbf{B}_{r,\tau} = 1$ indicates that the component is retained in the reconstruction. To prevent the mask from spreading too widely, when the nonzero ratio of $\mathbf{B}$ exceeds 0.2, we adaptively raise the threshold so that only the top 20% of activations are retained. Finally, the masked amplitude spectrogram corresponding to each array c is reconstructed by $\mathbf{W}(\mathbf{H}^{(c)} \odot \mathbf{B})$, where $\odot$ denotes the element-wise product. Combining the reconstructed amplitude spectrogram with the STFT phase of the beamforming output y_c of each array, we obtain a time-domain waveform for each array via the inverse STFT. The resulting reconstructed waveforms are averaged across arrays to obtain a single-channel reconstructed waveform $\hat{y}(t)$. From the waveform $\hat{y}(t)$, which reconstructs and integrates the common components extracted by NMF, we generate a noise-suppressed single-channel log-power spectrogram. Letting the STFT of $\hat{y}(t)$ be $\hat{Y}_{f,\tau}$, the final spectrogram is computed as in Eq. (16).

$$G(f, \tau) = 10 \log_{10} (|\hat{Y}_{f,\tau}|^2 + \epsilon) \quad (16)$$

Here, f is the frequency bin, τ is the time frame, and $\epsilon = 10^{-10}$ is a small positive constant that stabilizes the logarithm. The upper and lower bounds of the frequency band used differ between the simulation and real-robot evaluations; the specific values are given in Appendix A.3.

E Real-Robot Setup Details

This appendix describes the experimental setup for the real-robot experiments discussed in Section 4.2. As the evaluation policy, we adopted ACT, which showed stable performance on both the L&I task and the exploratory task in simulation, and compared the S2A2 model with the baseline. For each condition, we collected 100 episodes of demonstration data by human teleoperation, trained for 200,000 steps, and evaluated the success rate over 100 trials with a single seed. The environment setup for each task is described below.

In the L&I task, we used small Buffalo speakers (BSSP105UBK) as the sound sources. Each speaker has external dimensions of $64 \times 72 \times 60$ mm and a mass of about 210 g. To make the speakers easier for the manipulator to grasp, we wrapped yellow-green protective tape around the side of each speaker to form a handle of approximately 40 mm radius and 25 mm width. The two destination boxes for the speakers are black, with external dimensions of $60 \times 90 \times 90$ mm, and were each fixed 280 mm from the two ends of the table.

In the exploratory task, we prepared two visually identical black empty cans. Each can is 135 mm tall, with a diameter ranging from 40 mm at the top to 66 mm at the bottom. Only one of the two cans was filled with three metal nuts so that sound is produced when it is grasped and shaken. The gray destination box, measuring $95 \times 145 \times 230$ mm, was placed at the center of the table in front of the robot.

F Additional Real-Robot Experiment Sequences

This appendix presents figures of the real-robot experiments that could not be included in the main text, in Figs. 11 and 12.

G Detailed results

Performance degradation from mismatched or unnecessary acoustic representations. When an acoustic processing pipeline that did not provide task-relevant information was included, or when

Figure 11: Example real-robot sequence of the S2A2 model with ACT performing the L&I task.

Figure 12: Example real-robot sequence of the S2A2 model with ACT performing the exploratory task.

a representation required by the task was removed, performance sometimes fell below the vision-only baseline. Examples include the localization task under w/o Spat., where the model receives spectrogram features but lacks the acoustic spatial map needed to identify the sounding object, and Diffusion Policy on the exploratory task under w/o Spat., where using only the spectrogram pipeline degraded performance. These results suggest that, under demonstration data with limited quantity and diversity, policy networks may fail to ignore task-irrelevant acoustic inputs, and such inputs can hinder optimization.

Improvement from leveraging acoustic information. From the results in Table 2, the magnitude of improvement from adding acoustic information strongly depends on the policy. In particular, ACT and Diffusion Policy showed marked improvements over the baseline by adding acoustic information across all tasks. VQ-BeT, on the other hand, showed performance improvements over the baseline across all tasks, but the magnitude of these improvements was consistently smaller than that of ACT and Diffusion Policy. A possible cause is that VQ-BeT is designed to quantize actions into discrete codes, which may limit the expressiveness of the actions. For the S2A2 model with

π_0 , the success rate on the identification task approached that of ACT, which achieved the highest performance, whereas on the exploratory task it was the lowest among all policies. Because π_0 is a large-scale pretrained Vision-Language-Action (VLA) model, an integration of acoustic features that distorts the pretraining distribution may have led to the performance degradation. The exploratory task is particularly notable in that the improvement from leveraging acoustic information differs greatly across policies. For ACT, conditions that include either acoustic spatial information or acoustic signal information alone substantially exceeded the baseline, and the S2A2 model combining both showed a comparably high success rate. Since this task involves selecting the object whose sound was observed after grasping, either acoustic representation—acoustic spatial information or acoustic signal information—can be interpreted as providing the information needed for the conditional branching. On the other hand, for Diffusion Policy, VQ-BeT, and π_0 , the performance gains when combined with the S2A2 model were limited. In carrying out this relatively long-horizon task involving conditional branching, differences in the action expressiveness of the policies themselves and in the design of how acoustic features are integrated within the multimodal policy are considered to be factors causing the differences across policies.

H Simulation Setup Details

We use a Franka Emika Panda robot arm. The proprioception included in the observation is a 9-dimensional vector comprising the end-effector position, the rotation quaternion, and the 2-DoF gripper opening, and the action is a 9-dimensional position control command comprising the 7 joint position targets of the Franka and the 2-DoF gripper position target. As the visual information in the observation, we use two 224×224 RGB images obtained from the front and side cameras. The acoustic simulation uses a $10\text{ m} \times 10\text{ m} \times 3\text{ m}$ indoor environment and considers reflections up to the third order. The microphone arrays are placed at equal intervals on a circle of radius 300 mm around the workspace center. Based on the preliminary experiments shown in Appendix C, the number of microphone arrays is set to $N = 4$, the visual information is updated at 30 FPS, and the acoustic information at 10 FPS. In the exploratory task, one of the two objects is randomly selected per episode, and sound is produced when the movement speed of that object exceeds 0.5 mm/s. Two types of sound sources, sound type A and B, are prepared, with A being a bird call and B a buzzer sound. The localization and exploratory tasks use only sound A, while the identification and L&I tasks use both sounds A and B. Demonstrations for imitation learning were collected by generating trajectories with an expert that uses privileged information such as the position of the sound-emitting object and the sound label to specify the target end-effector pose at fixed time intervals, using the damped least-squares inverse kinematics of the Genesis library. We collected 100 episodes of demonstrations for the localization and identification tasks, and 200 episodes for the L&I and exploratory tasks. As the training setting, we trained for 100,000 steps on the localization and identification tasks, and for 200,000 steps on the L&I and exploratory tasks. The batch size was 4 for π_0 , 8 for ACT, and 32 for Diffusion Policy and VQ-BeT.
