Abstract. Clinical large language models (LLMs) are often scaled by increasing model size, context length, retrieval complexity, or inference-time compute, with the implicit expectation that higher accuracy implies safer behavior. This assumption is incomplete in medicine, where a few confident, high-risk, or evidence-contradicting errors can matter more than average benchmark performance. We introduce Safety-Focused Evaluation of Scaling (SaFE-Scale), a framework for measuring how clinical LLM safety changes across model scale, evidence quality, retrieval strategy, context exposure, and inference-time compute. To instantiate this framework, we introduce RadSaFE-200, a Radiology Safety-Focused Evaluation benchmark of 200 multiple-choice questions with clinician-defined clean evidence, conflict evidence, and option-level labels for high-risk error, unsafe answer, and evidence contradiction. We evaluated 34 locally deployed LLMs across six deployment conditions: closed-book prompting (zero-shot), clean evidence, conflict evidence, standard retrieval-augmented generation (RAG), agentic RAG, and max-context prompting. Clean evidence produced the strongest improvement, increasing mean accuracy from 73.5% to 94.1%, while reducing high-risk error from 12.0% to 2.6%, contradiction from 12.7% to 2.3%, and dangerous overconfidence from 8.0% to 1.6%. Standard RAG and agentic RAG did not reproduce this safety profile: agentic RAG improved accuracy over standard RAG (76.0% to 78.1%) and reduced contradiction (11.7% to 9.0%), but high-risk error and dangerous overconfidence remained elevated. Max-context prompting increased latency without closing the safety gap, and additional inference-time compute produced only limited gains. Worst-case analysis showed that clinically consequential errors concentrated in a small subset of questions. Clinical LLM safety is therefore not a passive consequence of scaling, but a deployment property shaped by evidence quality, retrieval design, context construction, and collective failure behavior.

Introduction

Large language models (LLMs) are increasingly being evaluated for clinical decision support, radiology education, evidence-grounded reasoning, and retrieval-assisted question answering [1,2,3,4,5]. In practice, deployment choices are often driven by scaling: larger models are preferred over smaller ones, longer contexts are assumed to provide more complete evidence, and additional inference-time compute is used to improve answer stability [6,7,8,9]. This strategy rests on an intuitive assumption

that higher average accuracy should translate into safer clinical behavior. In medicine, however, this assumption is incomplete. Safety is not defined only by whether a model selects the correct answer on average, but also by the kinds of mistakes it makes when it fails, whether those mistakes could alter clinical management, whether the model contradicts available evidence, and whether incorrect answers are delivered with high confidence [2,10,11].

Radiology is a particularly relevant domain in which to study this problem because radiology questions often combine image-derived findings, clinical context, diagnostic reasoning, and management-relevant distinctions [3,12]. Recent retrieval-augmented and agentic reasoning systems have improved radiology question answering by adding external evidence and multi-step synthesis to LLM inference [13,12]. Yet these systems also introduce new deployment dependencies. Retrieved evidence may be incomplete, noisy, or misleading; longer context may increase information exposure without improving reasoning; and structured reasoning can align models toward the same answer even when that answer is wrong [14,15,16,8,9]. Prior work has therefore shown that accuracy, factual grounding, and inter-model agreement are related but not interchangeable [12,17,18,19,20]. What remains less clear is how clinical safety behaves when the system is scaled along the axes that are most common in practice: model size, evidence condition, context exposure, and inference-time compute. The central challenge is that safety-relevant errors are sparse, asymmetric, and clinically structured [21,1,2]. A model may improve from 70% to 80% accuracy while retaining a small but unacceptable number of high-risk errors [21]. A retrieval system may reduce contradictions but leave dangerous overconfidence unchanged [17,10,11]. An ensemble may improve majority accuracy while preserving synchronized failures in which all members converge on the same wrong option [18,22]. These behaviors are not captured by conventional benchmark reporting, which usually treats all wrong answers as equivalent and focuses on mean accuracy as the primary endpoint [23,24,1]. For clinical LLM evaluation, this is a serious limitation because the clinical severity of errors, their relationship to provided evidence, and the confidence with which they are produced are central to deployment risk [1,21,10].

To address this gap, we constructed RadSaFE-200, a Radiology Safety-Focused Evaluation benchmark containing 200 multiple-choice questions pooled from previously published radiology question sets and newly curated cases [13,12]. Each question includes a correct option, clinician-written clean evidence, clinician-written conflict evidence, and option-level labels indicating whether each answer choice would constitute a high-risk error, an unsafe answer, or a contradiction to the provided evidence. This design allows every model output to be evaluated not only for correctness, but also for clinically meaningful safety behavior. RadSaFE-200 is therefore not intended as a conventional leaderboard, but as an instrument for measuring how safety changes under controlled deployment conditions. Using RadSaFE-200, we define Safety-Focused Evaluation of Scaling (SaFE-Scale), a framework for measuring how clinical LLM safety changes across model scale, evidence quality, retrieval strategy, context exposure, and inference-time compute (Fig. 1). We evaluated 34 LLMs spanning Qwen [25], Llama [26], Gemma [27] and MedGemma [28], DeepSeek [29,30], Mistral, and OpenAI-OSS [31] families. The main experiment compared six deployment conditions: closed-book prompting, clean evidence, conflict evidence, standard retrieval-augmented generation (standard RAG) [4], agentic retrieval-augmented generation (agentic RAG) [12], and max-context prompting [4]. Agentic RAG was implemented using the previously described radiology Retrieval and Reasoning framework [12]. We additionally performed targeted inference-time compute experiments using five-sample self-consistency in representative models and fixed three-model ensembles [9,18,22]. For every run, we recorded the selected option, confidence, and latency, and mapped the prediction to predefined safety labels. The primary outcomes were high-risk error rate, unsafe answer rate, contradiction rate, and dangerous overconfidence rate, with accuracy reported as an important but secondary endpoint.

The results show that clinical LLM safety is governed more strongly by evidence quality and deployment condition than by scale or inference-time compute alone. Clean clinician-written evidence produced the largest improvement in both accuracy and safety, increasing model-averaged accuracy from 73.5% to 94.1% while reducing high-risk error from 12.0% to 2.6% and dangerous overconfidence from 17.9% to 3.7%. In contrast, standard RAG and agentic RAG improved selected metrics but remained much closer to closed-book prompting than to clean evidence, and max-context prompting increased latency without closing the safety gap. Self-consistency provided only small gains, whereas ensembles improved aggregate performance but retained synchronized failures. The findings argue that safer clinical LLM deployment cannot be inferred from accuracy scaling alone. It requires direct measurement of safety under the evidence, context, and compute conditions in which the system will actually be used.

Results

All analyses use the pooled 200-question RadSaFE-200 benchmark, with no stratification by source subset. For each model response, the selected option was mapped to correctness and to the predefined option-level safety labels, yielding high-risk error, unsafe answer, and evidence-contradiction outcomes. Confidence and latency were recorded when available. The main SaFE-Scale experiment evaluated 34 LLMs across six deployment conditions: closed-book prompting, clean evidence, conflict evidence, standard RAG [4], agentic RAG [12], and max-context prompting [8]. Standard RAG [4] and agentic RAG [12] used Radiopaedia [32] as the external evidence source, with agentic RAG implemented using the previously described radiology Retrieval-and-Reasoning (RaR) framework [12]. Two secondary experiments probed inference-time compute using self-consistency [9] in eight representative models and majority-vote ensembling [18,22] using four fixed three-model ensembles. Throughout this section, accuracy is reported as model-averaged percentage with standard deviation and 95% confidence intervals (CIs). Safety metrics, confidence, and latency are reported in percent, percent, and seconds, respectively. Model-averaged values across the six deployment conditions are summarized in Table 1 and serve as the reference point for the analyses that follow.

Safety and accuracy decouple across deployment conditions

A central observation across the 34-model panel is that accuracy and safety responded differently to changes in deployment strategy. The accuracy-vs-high-risk and accuracy-vs-dangerous-overconfidence planes shown in Fig. 2a,b reveal that condition centroids do not move along a single trade-off curve: clean and conflict evidence land near the safe deployment region (accuracy ≥ 90 , high-risk error ≤ 5), while standard RAG, agentic RAG, and max-context prompting cluster well below it despite differing accuracy values. The transition from standard RAG to agentic RAG is the clearest example of decoupling visible in the figure: the centroid moves to higher accuracy but to higher dangerous overconfidence, reversing the direction one would expect under a single-axis improvement.

The largest unified shift in both accuracy and safety came from clinician-written clean evidence. Averaged over the 34 evaluated LLMs, accuracy increased from 73.5 ± 2.9 [67.7, 79.2] under closed-book prompting to 94.1 ± 1.6 [90.7, 97.0] with clean evidence, a 20.6 percentage-point gain (Table 1). Parallel reductions were observed in every safety metric: high-risk error decreased from 12.0 to 2.6, unsafe answers from 1.8 to 0.2, contradiction from 12.7 to 2.3, and dangerous overconfidence from 8.0 to 1.6. The paired model-level transitions in Fig. 2c show that this shift was not driven by a few strong models: every one of the 34 models moved toward higher accuracy and lower high-risk error under clean evidence, with most landing inside the safe deployment region. Fig. 1: Overview of the SaFE-Scale evaluation framework. **a** Motivating example showing that the same incorrect label can correspond to clinically different outcomes: a safe and confident answer, a high-risk error, or a dangerously overconfident high-risk error. **b** Four evaluation axes used throughout the study: accuracy, high-risk error rate, unsafe answer rate, and dangerous overconfidence rate. Accuracy captures correctness, whereas the other axes characterize the clinical safety of wrong answers. **c** Six deployment conditions spanning no external evidence, curated evidence, conflicting evidence, retrieval, agentic retrieval, and long-context prompting. **d** Evaluation panel consisting of RadSaFE-200, a 200-question radiology benchmark with 4–5 answer choices and option-level safety labels, and 34 LLMs from seven model families. **e** Main factorial experiment crossing 34 models, 6 deployment conditions, and 200 questions, yielding 40,800 model-condition-question evaluations. Two secondary experiments probe inference-time compute using self-consistency and fixed three-model ensembles. **f** Roadmap of the main analyses, linking the framework to the subsequent figures on deployment-condition decoupling, confidence, scaling, self-consistency, and ensembling.

Table 1: Model-averaged performance across deployment conditions on RadSaFE-200. Values are averaged over the 34 evaluated LLMs and computed on the pooled 200-question benchmark. Each row corresponds to one deployment condition, with accuracy, safety metrics, confidence metrics, and latency grouped into compact columns to reduce horizontal width. Accuracy is reported as mean $\pm$ standard deviation with 95% confidence intervals in brackets. All other values are reported in percent except latency, which is reported in seconds. Safety metrics are derived by mapping each selected option to clinician-defined option-level labels. Agentic RAG was implemented using the previously described radiology Retrieval and Reasoning framework.

Condition	Accuracy	Safety metrics		Confidence and latency	
Closed-book	73.5 $\pm$ 2.9 [67.7, 79.2]	High-risk error	12.0	Mean conf.	92.9
		Unsafe answer	1.8	Conf. correct	94.9
		Contradiction	12.7	Conf. incorrect	86.8
		Dangerous overconf.	8.0	Conf. high-risk	87.8
				Conf. unsafe	83.8
				Latency (s)	18.0
Clean evidence	94.1 $\pm$ 1.6 [90.7, 97.0]	High-risk error	2.6	Mean conf.	97.6
		Unsafe answer	0.2	Conf. correct	98.5
		Contradiction	2.3	Conf. incorrect	87.5
		Dangerous overconf.	1.6	Conf. high-risk	85.4
				Conf. unsafe	80.8
				Latency (s)	17.3
Conflict evidence	92.5 $\pm$ 1.8 [88.8, 95.7]	High-risk error	3.5	Mean conf.	97.3
		Unsafe answer	0.2	Conf. correct	98.3
		Contradiction	2.6	Conf. incorrect	87.1
		Dangerous overconf.	2.3	Conf. high-risk	88.3
				Conf. unsafe	88.9
				Latency (s)	17.5
Standard RAG	76.0 $\pm$ 2.8 [70.5, 81.4]	High-risk error	9.6	Mean conf.	92.0
		Unsafe answer	1.9	Conf. correct	94.6
		Contradiction	11.7	Conf. incorrect	84.5
		Dangerous overconf.	5.7	Conf. high-risk	85.8
				Conf. unsafe	84.7
				Latency (s)	18.4
Agentic RAG	78.1 $\pm$ 2.8 [72.6, 83.3]	High-risk error	10.3	Mean conf.	95.4
		Unsafe answer	1.6	Conf. correct	96.8
		Contradiction	9.0	Conf. incorrect	90.6
		Dangerous overconf.	8.0	Conf. high-risk	93.0
				Conf. unsafe	89.3
				Latency (s)	19.9
Max context	74.0 $\pm$ 2.9 [68.4, 79.5]	High-risk error	10.6	Mean conf.	88.8
		Unsafe answer	2.0	Conf. correct	91.6
		Contradiction	11.6	Conf. incorrect	79.4
		Dangerous overconf.	6.0	Conf. high-risk	81.4
				Conf. unsafe	79.7
				Latency (s)	27.0

stratification showed the same direction of change for accuracy and high-risk error from closed-book prompting to clean evidence across all subspecialty strata, although small strata should be interpreted cautiously (Supplementary Table 1).

Conflict evidence served as a stress test for whether models remained safe when the provided context contained a distracting or partially conflicting statement. Compared with clean evidence, conflict evidence produced a 1.6 percentage-point reduction in accuracy, from 94.1 ± 1.6 [90.7, 97.0] to 92.5 ± 1.8 [88.8, 95.7], while high-risk error rose from 2.6 to 3.5, contradiction from 2.3 to 2.6, and dangerous overconfidence from 1.6 to 2.3. Unsafe answers remained at 0.2 in both conditions. Mean confidence declined only marginally, from 97.6 to 97.3, while confidence among high-risk errors increased from 85.4 to 88.3 (Table 1). Conflict evidence therefore degrades safety in a measurable but graded fashion: even a single distracting statement increases high-risk and overconfident failures before any large accuracy collapse becomes visible.

Max-context prompting produced almost no accuracy gain over closed-book prompting, reaching 74.0 ± 2.9 [68.4, 79.5], while increasing mean latency from 18.0 to 27.0 seconds, with high-risk error at 10.6 and dangerous overconfidence at 6.0. The latency-vs-accuracy view in Fig. 2g makes the cost structure visible: clean evidence achieves the strongest accuracy and safety profile at a mean latency of 17.3 seconds, whereas the more compute-intensive conditions either fail to recover accuracy (max context) or recover accuracy without recovering safety (agentic RAG). Latency stratified by model-size bucket is provided in Supplementary Table 2. The five-axis safety profile in Fig. 2f reinforces this conclusion: only clean and conflict evidence span the entire reliability polygon, while the three retrieval and long-context conditions retain visible deficits on at least one safety axis.

Confidence is not a reliable signal for unsafe behavior

Because clinical deployment depends on whether a model’s confidence can be trusted [33,34], we examined how reported confidence behaves on correct, incorrect, high-risk, and unsafe outputs. The per-outcome distributions in Fig. 3a show that confidence is uniformly high across all four classes under every deployment condition, with the median confidence on high-risk and unsafe outputs sitting only a few percentage points below the median on correct outputs. Under closed-book prompting, mean confidence was 93.4 overall, 95.3 among correct answers, 87.8 among incorrect answers, 87.8 among high-risk errors, and 83.8 among unsafe answers (Table 1). Clean evidence reduced the frequency of dangerous errors but did not make residual errors low-confidence: confidence among incorrect answers remained at 88.4, while confidence among high-risk and unsafe answers was 85.4 and 80.8, respectively. Therefore, the safety benefit of clean evidence comes from reducing the number of unsafe responses, not from making the residual errors uncertain.

The size of the per-model gap between confidence on correct and high-risk answers, summarized in Fig. 3b, quantifies how poorly confidence discriminates safety. The median gap remained well below 30 percentage points across all four examined conditions, which is the threshold above which confidence could plausibly serve as a deployment filter. The relationship between accuracy and confidence among incorrect answers (Fig. 3c) was approximately flat: models with very different accuracies still reported similar confidence on the questions they got wrong. The scatter of confidence on high-risk errors against confidence on correct answers (Fig. 3d) lies almost entirely along the $y = x$ diagonal, meaning that for almost every model, the confidence with which it asserts a clinically dangerous wrong answer is indistinguishable from the confidence with which it asserts a correct one.

The dangerous overconfidence metric, which jointly requires incorrectness, a clinically risky selected option, and entropy-normalised repeated-sampling confidence at or above 0.80, showed the clearest separation between deployment conditions. Closed-book to clean evidence improved

Fig. 2: Safety and accuracy decouple across deployment conditions on RadSaFE-200. In all panels except **f**, each small marker corresponds to one of the 34 evaluated LLMs under the indicated condition; stars denote condition centroids (model-averaged values). **a** Per-model accuracy vs. high-risk error rate across all six deployment conditions. The shaded region marks the safe deployment regime (accuracy $\geq 90\%$, high-risk error $\leq 5\%$). **b** Per-model accuracy vs. dangerous overconfidence rate across the same conditions. The black arrow marks the standard-RAG to agentic-RAG centroid shift. **c–e** Paired condition transitions for each of the 34 models. Thin gray lines connect the same model across the two conditions; the thick black arrow shows the centroid shift. Panels show closed-book to clean evidence (**c**), closed-book to standard RAG (**d**), and standard RAG to agentic RAG (**e**). Panels **c** and **d** use the (accuracy, high-risk error) plane; panel **e** uses the (accuracy, dangerous overconfidence) plane. **f** Model-averaged safety profile across five normalized axes: accuracy, 1–high-risk error, 1–unsafe answer, 1–contradiction, and 1–dangerous overconfidence. Higher values indicate better behavior on all axes. **g** Per-model accuracy vs. mean per-question latency on a logarithmic scale. Marker size is inversely proportional to dangerous overconfidence rate, so larger markers indicate safer behavior. Across all panels, accuracy and safety metrics are reported in percent; latency is reported in seconds.

dangerous overconfidence in all 34 of 34 models (Fig. 3e), consistent with the broad shift seen on accuracy. The corresponding closed-book to agentic-RAG transition (Fig. 3f) was non-uniform: 17 of 34 models improved while 15 worsened, indicating that retrieval that increases accuracy can simultaneously raise the rate of confident high-risk errors. The condition-level heatmap in Fig. 3g makes this pattern explicit: the columns corresponding to clean and conflict evidence are uniformly cool across all 34 models, whereas the standard-RAG, agentic-RAG, and max-context columns remain warm regardless of model identity. Confidence should therefore be interpreted as a clinical safety signal in addition to a calibration statistic [34,35,10,11]: models can be high in confidence precisely on the subset of errors most relevant to clinical harm.

Safety and accuracy follow different scaling laws

To test whether the observed deployment-level effects could simply be absorbed into a model-scaling story [6,7], we examined how accuracy and safety vary with model parameter count and family. The scaling triplet in Fig. 4a–c plots per-model accuracy, high-risk error, and dangerous overconfidence on a logarithmic parameter axis, with closed-book values shown as filled circles and clean-evidence values as open stars. Within-family curves under closed-book prompting fan out widely with parameter count: accuracy ranged from 41.5 at the smallest scale to 88.4 at the largest within the same panel, and family-level closed-book accuracy varied from 68.2 (MedGemma) to 86.4 (DeepSeek). Under clean evidence, the same families collapsed to a narrow ceiling band: accuracy reached 97.0 for DeepSeek, 95.4 for Qwen, 95.2 for Mistral, 94.0 for Gemma, 93.5 for OpenAI-OSS, 92.4 for MedGemma, and 90.4 for Llama, and the corresponding clean-evidence high-risk error rates were 1.5, 2.1, 2.3, 2.9, 2.2, 3.5, and 3.7, respectively. The largest absolute accuracy gains were observed in Qwen and Gemma, both increasing by 24.7 percentage points, followed by MedGemma at 24.2 and Llama at 20.2. The families with the weakest closed-book performance therefore gained the most from curated evidence, an equalization pattern visible in Fig. 4g.

To quantify the relative contributions of model family, deployment condition, and their interaction, we performed a two-way variance decomposition of each metric across the full 34-model, 6-condition grid. Deployment condition explained 43, 45, and 38 percent of the variance in accuracy, high-risk error, and dangerous overconfidence, respectively, while model family explained only 9, 8, and 17 percent. The family-by-condition interaction accounted for 6, 4, and 8 percent (Fig. 4d). The family-by-condition heatmap in Fig. 4e makes the same observation visually: the column dimension dominates the row dimension, with the clean and conflict columns uniformly cool regardless of family, while standard RAG, agentic RAG, and max context remain warm for every family. Within-family standard deviation of high-risk error provides a third view of the same effect (Fig. 4f): the mean within-family spread collapses from 3.8 percentage points under closed-book prompting and 3.6 under standard RAG to 1.0 under clean evidence and 1.2 under conflict evidence. Curated evidence therefore not only lowers high-risk error on average, it also sharply reduces the variability of high-risk error among models of the same family. Taken together, these results indicate that scaling alone, whether measured by parameter count, family choice, or even matched-scale within-family comparisons, does not approximate the effect of providing high-quality clinical evidence.

Self-consistency provides limited safety gains

We next assessed whether inference-time compute [36], in the form of self-consistency [9], could close the safety gap left by deployment infrastructure and model scale. Self-consistency aggregates multiple independent samples per question by majority vote and replaces single-sample greedy decoding with a repeated-sampling majority vote [9]. The experiment was performed on a targeted

Fig. 3: Confidence is not a safety signal under any deployment condition. **a** Per-model mean confidence under four representative deployment conditions, broken down by outcome class: correct answers, incorrect answers, high-risk errors, and unsafe answers. Each box-and-strip element shows the distribution across the 34 models, with the median marked by the black line; black dots are individual models. **b** Per-model confidence gap between correct answers and high-risk errors, by deployment condition. Each dot is one model; black bars and adjacent values indicate medians. **c** Per-model mean confidence among incorrect answers as a function of accuracy, with one point per model and condition. The dashed line is the linear fit pooled across all conditions. **d** Per-model mean confidence among high-risk errors vs. mean confidence among correct answers, with one point per model and condition. **e,f** Paired per-model dangerous overconfidence rates under closed-book vs. clean evidence (**e**) and closed-book vs. agentic RAG (**f**). Connector color indicates the direction of change (gray, no change or improvement; red, worsening). Vertical dotted lines mark the median value in each condition. **g** Per-model dangerous overconfidence rate across deployment conditions.

Fig. 4: Safety and accuracy follow different scaling laws on RadSaFE-200. **a–c** Per-model values plotted against model parameter count on a logarithmic axis, for accuracy (**a**), high-risk error rate (**b**), and dangerous overconfidence rate (**c**). Marker colour denotes model family. Filled circles show closed-book values and open stars show clean-evidence values; thin solid and dashed lines connect within-family closed-book and clean-evidence points, respectively. Horizontal dotted lines mark the model-averaged values for closed-book (gray) and clean evidence (blue). **d** Two-way decomposition of the variance in each metric across model family and deployment condition, into condition, family, family $\times$ condition interaction, and residual components. **e** Heatmap of family-mean high-risk error rate across model families and deployment conditions. **f** Within-family standard deviation of high-risk error rate per deployment condition. Bar height is the mean across families; coloured dots show per-family values. **g** Family-level change from closed-book to clean evidence. Signs of the two safety metrics are flipped so that positive values indicate improvement. Across all panels, accuracy and rates are reported in percent and parameter counts in billions.

subset of eight models under three deployment conditions (closed-book, conflict evidence, standard RAG); condition-averaged results are summarized in Table 2.

The Single-to-self-consistency transitions in Fig. 5a–c show small condition-mean shifts in accuracy and approximately stationary high-risk and unsafe rates. Condition-mean accuracy changed by +0.6 percentage points under closed-book prompting, +0.1 under conflict evidence, and +0.4 under standard RAG. The corresponding high-risk error changes were -0.4 , $+0.1$, and -0.5 , respectively, and unsafe-answer changes were essentially zero across all three conditions. The joint Single-to-self-consistency change plot in Fig. 5d places most (model, condition) pairs near the origin and slightly into the upper-right quadrant, indicating that small accuracy gains and small safety gains co-occur but neither effect is large.

Because dangerous overconfidence requires an aggregated probability, it is defined only under self-consistency. Across the 24 (model, condition) pairs shown in Fig. 5e, dangerous overconfidence under self-consistency ranged moderately, with model-level values reaching 15.5 under closed-book prompting and 10.5 under standard RAG, while remaining low under conflict evidence at values from 0.5 to 4.0. The relationship between mean self-consistency confidence and self-consistency high-risk error (Fig. 5f) is essentially flat near a high common confidence level: the overall mean confidence across all (model, condition) pairs was 96.8, and points with very different high-risk error rates report nearly identical confidences. Aggregating across all 24 pairs, the mean Single-to-self-consistency change (Fig. 5g) was +0.39 percentage points for accuracy, +0.27 for high-risk safety, +0.02 for unsafe-answer safety, and +0.17 for contradiction safety, with standard errors of similar magnitude in each case. Under conflict evidence specifically, accuracy moved by only +0.1 percentage points and high-risk error by +0.1, both within sampling noise. Therefore, in this experiment, self-consistency provides modest accuracy and safety gains that fall well short of the effect of curated evidence. Increasing inference-time sampling is not, by itself, a major safety intervention.

Ensembles improve aggregate performance but introduce synchronized failure

To complete the picture of inference-time strategies, we evaluated four fixed three-model majority-vote ensembles [37,38,18] under three deployment conditions: Dense Mid (similar-scale open dense models), Frontier (largest open and closed models), Qwen scale (within-family scale diversity), and Cross scale (cross-family mixed scale). Member-level results were taken from the same 34-model panel used elsewhere in the paper, allowing direct comparison between each ensemble and its individual members.

Ensembles improved aggregate accuracy and high-risk error relative to the panel average, but they did not consistently outperform the strongest individual member. Under closed-book prompting, the four ensembles reached an average accuracy of 83.0 with average high-risk error 7.4, compared with 73.5 and 12.0 for the 34-model average (Table 3). Under conflict evidence, ensembles averaged 94.9 accuracy, 2.6 high-risk error, 1.6 contradiction, and 2.4 dangerous overconfidence. Under standard RAG, ensembles averaged 85.5 accuracy and 5.5 high-risk error compared with 76.0 and 9.6 for the panel average. The per-(ensemble, condition) views in Fig. 6a–c show, however, that the ensemble star typically lands inside or just above the cluster of its three member dots, rather than beating the safest member. Aggregated across all 12 cases, the ensemble’s mean change relative to its best individual member was -0.88 percentage points for accuracy, -0.79 for high-risk safety, 0.00 for unsafe-answer safety, and -1.67 for dangerous-overconfidence safety (Fig. 6f). The corresponding per-member breakdown is provided in Supplementary Table 3. Ensembles therefore behaved as a regression toward the center of the member panel rather than as a strict safety improvement over the best available model.

Fig. 5: Inference-time compute via self-consistency (SC) does not produce safety. Eight models are evaluated under three deployment conditions, each in a single-sample regime (Single) and an SC regime aggregating eight samples. **a–c** Per-(model, condition) Single-to-SC transitions for accuracy (**a**), high-risk error rate (**b**), and unsafe answer rate (**c**). Thin lines connect the same model under the same condition; thick lines and large markers show the condition mean. Δ values report the change in the condition-mean. **d** Joint Single-to-SC change in accuracy and in high-risk safety, where high-risk safety is defined as Single minus SC high-risk error rate. **e** SC dangerous overconfidence rate per model and condition, with models sorted by across-condition mean. **f** Mean SC confidence vs. SC high-risk error rate, one point per (model, condition). The dotted line marks the overall mean confidence. **g** Mean Single-to-SC change across all 24 (model, condition) pairs. Bars show means and whiskers show ± 1 SEM. Safety-metric signs are flipped so that positive values indicate improvement.

Table 2: Average effect of self-consistency in the targeted inference-time compute experiment. Values are averaged across the eight selected models. The table is organized as one block per deployment condition, with metrics shown as rows and inference regimes shown as columns. Single inference used greedy decoding, whereas self-consistency used eight samples per question followed by majority voting. Accuracy is reported as mean $\pm$ standard deviation [95% CI]. Dangerous overconfidence and mean confidence are defined over the eight self-consistency samples and are undefined for the single greedy regime in the provided results. Values are reported as percentages except latency, which is reported in seconds.

Metric	Single	Self-consistency
Closed-book		
Accuracy	79.3 $\pm$ 2.7 [73.9, 84.4]	80.0 $\pm$ 2.7 [74.6, 85.0]
High-risk error	9.4	9.1
Unsafe answer	1.1	1.1
Contradiction	9.4	9.1
Dangerous overconf.	–	6.9
Mean conf.	–	96.7
Latency (s)	42.0	42.0
Robustness correctness	–	79.8
Conflict evidence		
Accuracy	94.5 $\pm$ 1.6 [91.3, 97.4]	94.6 $\pm$ 1.6 [91.4, 97.4]
High-risk error	2.8	2.8
Unsafe answer	0.3	0.2
Contradiction	1.6	1.8
Dangerous overconf.	–	2.2
Mean conf.	–	99.2
Latency (s)	40.3	40.3
Robustness correctness	–	94.6
Standard RAG		
Accuracy	80.8 $\pm$ 2.6 [75.7, 85.7]	81.2 $\pm$ 2.6 [76.2, 86.1]
High-risk error	7.4	6.9
Unsafe answer	1.1	1.1
Contradiction	9.1	8.8
Dangerous overconf.	–	4.8
Mean conf.	–	94.6
Latency (s)	45.7	45.7
Robustness correctness	–	80.4

The clearest deployment-relevant finding is that ensembles introduce a new failure mode: synchronized failure, defined as a question on which all three members produce the same incorrect answer [22]. Synchronized failure averaged 5.9 under closed-book prompting and 6.5 under standard RAG, with the Frontier ensemble reaching 9.0 under standard RAG (Table 3, Fig. 6d). The synchronized-failure-vs-high-risk-error scatter in Fig. 6e places most (ensemble, condition) points on or directly below the $y = x$ diagonal, meaning that many of the ensemble’s high-risk errors are unanimous across its three members. Per-ensemble dangerous overconfidence under each condition (Fig. 6g) follows the same pattern observed for individual models: it remains 4.0–7.5 under closed-book prompting and 4.0–5.5 under standard RAG, but drops to 2.0–3.0 under conflict evidence. Agreement among strong models is therefore not equivalent to clinical safety [22]: when the underlying members fail, they tend to fail together and to do so with high confidence, particularly under closed-book prompting and standard RAG.

Table 3: Performance of fixed three-model ensembles on RadSaFE-200. The table is organized as one vertically stacked block per ensemble, with deployment conditions shown as columns and evaluation metrics shown as rows. Each block lists the three ensemble members and purpose once, followed by majority-vote performance under closed-book prompting, conflict evidence, and standard RAG. Synchronized failure is defined as the fraction of questions for which all three ensemble members selected the same wrong option. Accuracy is reported as mean $\pm$ standard deviation [95% CI]. Values are reported as percentages.

Fig. 6: Ensembling does not produce safety, and introduces synchronized failure as a new failure mode. 4 three-member ensembles are evaluated under 3 deployment conditions: Dense Mid (similar-scale open dense models), Frontier (largest open and closed models), Qwen scale (within-family scale diversity), and Cross scale (cross-family mixed scale). **a–c** Per-(ensemble, condition) accuracy (**a**), high-risk error rate (**b**), and dangerous overconfidence rate (**c**). Each ensemble is shown as a star colored by condition; the three corresponding member values are shown as gray dots connected by a vertical line. **d** Synchronized failure rate per ensemble and condition, where synchronized failure denotes a question on which all three members produced the same incorrect answer. **e** Per-(ensemble, condition) synchronized failure rate vs. high-risk error rate. Marker shape encodes the ensemble; marker color encodes the condition. Dashed diagonal marks the upper bound at which every high-risk error is a synchronized failure. **f** Mean change of each metric relative to the best individual member, averaged across all 4 ensembles $\times$ 3 conditions = 12 cases. Bars show means and whiskers ± 1 SEM. Safety-metric signs are oriented so that positive values indicate the ensemble outperforms its best member. **g** Dangerous overconfidence rate per ensemble and condition.

Worst-case failures concentrate in a small subset of questions

Clinically consequential failures were not evenly distributed across RadSaFE-200 [21,39]. Under closed-book prompting, the highest-risk questions formed a small set of recurrent failure cases in which many models selected the same clinically undesirable answer. The 15 highest-ranked questions all produced high-risk errors in more than half of the 34-model panel, with high-risk error rates ranging from 52.9 to 97.1 (Table 4). The full per-question distribution shows the same long-tail structure and demonstrates that clean evidence compresses this tail, reducing the mean per-question high-risk error rate from 12.0% to 2.6% (Supplementary Fig. 1). The same concentration pattern persisted when failures were ranked across all six deployment conditions: the 30 highest-risk questions by mean high-risk error rate remained dominated by recurrent diagnostic failure cases, with several questions retaining high-risk error rates above 60% even after averaging across closed-book prompting, evidence-based prompting, retrieval, agentic RAG, and max-context prompting (Supplementary Table 4). The highest-ranked question was answered incorrectly by all 34 models, produced high-risk errors in 33 models, and produced contradictions in all 34 models, corresponding to a wrong-answer rate of 100.0, a high-risk error rate of 97.1, and a contradiction rate of 100.0.

This question-level concentration shows that the safety signal in the benchmark is structured rather than random. Some cases were dominated by high-risk errors without evidence contradiction, whereas others combined high-risk errors with widespread contradiction, such as questions 53, 43, 49, 24, 199, 54, and 27. Notably, unsafe-answer labels did not drive the highest-risk closed-book ranking: the top 15 questions had unsafe answer rates of 0.0, and the dominant failure mode in this subset was clinically high-risk misclassification, often accompanied by contradiction. The overlap between this set and the synchronized-failure cases identified in the ensemble experiment (Fig. 6d,e) is therefore informative for deployment: the same questions that defeat individual models also tend to defeat agreement among strong models, which is precisely the regime in which a downstream user would have the strongest false sense of reassurance. Worst-case analysis at the question level therefore complements the aggregate metrics reported above [39,21] and identifies the specific cases against which any future intervention, whether evidence-based, retrieval-based, scale-based, or ensemble-based, should be evaluated.

Discussion

Using SaFE-Scale on RadSaFE-200, this study shows that clinical LLM safety cannot be inferred from accuracy alone [2,21]. Across 34 models and six deployment conditions, the largest improvement in both performance and safety came not from model scale [6,7], longer context [8], retrieval [4], agentic reasoning [12], self-consistency [9], or ensembling [38,18], but from the quality of the evidence supplied to the model. Clean clinician-written evidence increased mean accuracy from 73.5% to 94.1%, while reducing high-risk error from 12.0% to 2.6%, contradiction from 12.7% to 2.3%, and dangerous overconfidence from 8.0% to 1.6% (Table 1). This is the central finding of the paper. It suggests that safety in clinical LLM systems is not simply a property of the base model, nor a passive consequence of scaling [2,21]. It is a deployment property that depends strongly on the structure, quality, and clinical reliability of the information placed in front of the model [2,17,16].

The results also clarify what retrieval-based systems currently do and do not solve [4,17,16]. Standard RAG and agentic RAG improved selected outcomes relative to closed-book prompting, but neither reproduced the safety profile of curated evidence. Agentic RAG increased accuracy compared with standard RAG and reduced contradiction, which is consistent with better evidence integration [12]. However, high-risk error and dangerous overconfidence remained high, and dangerous overconfidence was higher under agentic RAG than under standard RAG. This distinction

Table 4: Highest-risk question-level failures under closed-book prompting. Questions are ranked by high-risk error rate, then unsafe answer rate, then contradiction rate. Counts are calculated over the 34 evaluated models. Each row corresponds to one question and reports the question number, question metadata, failure counts, and failure rates. Rates are reported in percent.

Question number	Question metadata	Failure counts ($n/34$)		Failure rates (%)	
53	<i>Subspecialty:</i> neuroradiology; pediatrics	Wrong	34	Wrong	100.0

is important. The result does not mean that agentic RAG is ineffective; rather, it shows that improving answer accuracy and evidence use is not the same as eliminating clinically consequential failure modes [2,21]. In clinical settings, a retrieval pipeline should therefore not be judged only by whether it improves the final answer rate [17,16]. It should also be tested for the residual errors it leaves behind, especially when those errors are high-risk and confidently stated [10,11].

The comparison between clean evidence and conflict evidence provides a useful boundary condition. Conflict evidence produced only a modest decrease in accuracy relative to clean evidence, from 94.1% to 92.5%, and only small increases in high-risk error, contradiction, and dangerous overconfidence. This suggests that the models were not globally brittle to mild evidence conflict. At the same time, safety degraded measurably before accuracy collapsed. This is precisely the kind of behavior that conventional benchmark reporting can miss [39,21]. A model may remain highly accurate while becoming less safe in the subset of cases where evidence is distracting, incomplete, or partially inconsistent [15,16,14]. Since real clinical evidence is rarely as clean as a benchmark context, this finding supports the need to evaluate retrieval-augmented systems under evidence perturbations rather than only under ideal evidence conditions [17,16].

A second major finding is that confidence was not a reliable safeguard [34,33,10]. Confidence remained high not only for correct answers, but also for incorrect, high-risk, and unsafe answers. Under closed-book prompting, mean confidence among high-risk errors was 87.8%, and under agentic RAG it was 93.0%. Clean evidence reduced the number of dangerous errors, but residual errors remained confidently expressed. This means that confidence cannot be treated as a simple safety filter [35,10,11]. In practice, a downstream system that suppresses only low-confidence answers would miss many of the errors that matter most. The dangerous-overconfidence metric was therefore useful because it links three clinically relevant elements: the model is wrong, the selected option is clinically risky, and the model is highly confident. This combined metric revealed safety failures that would be hidden if confidence and correctness were analyzed separately [34,10,21].

The scaling analysis further supports the main conclusion. Model family and parameter count influenced closed-book performance, but deployment condition explained more variance in accuracy, high-risk error, and dangerous overconfidence than model family. Clean evidence compressed differences between families and sharply reduced within-family variability in high-risk error. This does not imply that model scale is irrelevant [6,7]. Larger or stronger families often started from better closed-book baselines. However, scale did not substitute for reliable evidence. The practical implication is that choosing a larger model may improve baseline performance, but it does not remove the need for evidence-quality controls, safety-specific evaluation, and explicit monitoring of high-risk failure modes [2,21].

The inference-time compute experiments point in the same direction [36]. Self-consistency produced only small changes in accuracy and safety across the selected models and conditions [9]. Its average gains were far smaller than those obtained by clean evidence. This suggests that repeated sampling and majority voting cannot be assumed to transform an unsafe deployment condition into a safe one. Fixed ensembles improved aggregate performance relative to the full panel average [38,18], but they introduced a separate systems-level concern: synchronized failure [22]. In several settings, all three ensemble members selected the same wrong option, and many ensemble high-risk errors were unanimous among members. This matters because agreement among models can create a false sense of reliability [22]. In clinical use, a unanimous wrong answer may be more persuasive to a user than a single-model error, even though the underlying clinical risk is greater [21,33].

The worst-case analysis shows why aggregate metrics are not sufficient [39,21]. High-risk failures concentrated in a small subset of questions, with the 15 highest-risk questions producing high-risk errors in more than half of the model panel. The top-ranked case produced wrong answers in all 34 models, high-risk errors in 33 models, and contradictions in all 34 models. These failures were not random noise around the mean; they were structured, recurrent, and often shared across

models [22]. This has two implications. First, safety evaluation should include question-level failure analysis rather than only model-level averages [39,21]. Second, future mitigation methods should be tested directly on these recurrent failure cases, because improvements that do not address the worst cases may have limited clinical value.

These findings motivate a shift in how clinical LLM systems are evaluated [2]. The usual hierarchy of deployment assumptions is that larger models [6,7], longer context [8], more retrieval [4], and more inference-time compute [36,9] should progressively improve reliability. Our results show a different hierarchy. Clean, clinically relevant evidence produced the largest safety shift. Retrieval and agentic reasoning improved some metrics but left clinically important residual errors. Longer context increased latency without closing the safety gap. Self-consistency and ensembling improved selected aggregate metrics but did not eliminate high-confidence or synchronized failures. Therefore, clinical safety should be evaluated as a multi-dimensional deployment outcome, not as a single model capability [21]. RadSaFE-200 was designed to make this type of evaluation possible, and SaFE-Scale provides the experimental structure for applying it across model scale, evidence quality, retrieval strategy, context exposure, and inference-time compute. The contribution is not only that RadSaFE-200 adds another radiology question answering (QA) dataset, but that it maps each selected option to clinically meaningful safety labels. This allows a wrong answer to be treated differently depending on whether it is merely incorrect, high-risk, unsafe, or contradictory to evidence. That structure is essential for clinical benchmarking because not all errors have the same consequences [21,2]. A benchmark that only records final correctness cannot distinguish a benign distractor from a management-changing error, and cannot identify whether an incorrect answer is confidently asserted despite contradicting the supplied evidence [39,10]. By adding this safety layer, RadSaFE-200 makes it possible to evaluate deployment strategies in a way that is closer to clinical risk than ordinary accuracy reporting [21].

This study has several limitations. First, the benchmark is text-based and multiple-choice. This design enables controlled, reproducible scoring across many models and deployment conditions, but it does not capture the full complexity of radiology practice, where image interpretation, report context, longitudinal comparison, and open-ended reasoning interact [40,41,42]. Future work should extend this framework to multimodal radiology tasks and free-text clinical outputs [40,41,42]. Second, RadSaFE-200 contains 200 questions. Although the questions are clinically curated and the evaluation covers a large model panel, larger benchmarks will be needed to support more precise subgroup analyses by subspecialty, question type, and clinical risk category [21]. The newly curated Radiopaedia-derived questions were also primarily diagnostic or classification-oriented, reflecting the structure of available Radiopaedia cases; consequently, RadSaFE-200 is not fully balanced across question types. Third, the safety labels depend on predefined option-level annotations and necessarily include clinical judgement [21]. Although the annotations followed a rule set, assigning high-risk, unsafe, and contradiction labels was sometimes subjective because several questions required implicit assumptions about how an answer choice would translate into clinical action. This was particularly relevant for technically oriented, radiation therapy, physics, and negation-type questions, where the clinical consequence of selecting an option was less direct than in ordinary diagnostic questions. For negation-type questions, annotation required an additional counterfactual step, namely considering what would happen if a clinician misinterpreted the correct or incorrect status of an option and acted accordingly. Subspecialty assignment also required pragmatic mapping in some cases, especially for questions involving general imaging techniques such as radiography. These considerations do not invalidate the safety labels, but they mean that the labels should be interpreted as clinically informed severity annotations rather than fully objective ground truth. Future versions of RadSaFE should include multiple independent radiologist annotators, inter-rater agreement analysis, adjudication of disagreement, and more explicit annotation rules for technical, physics, radiation therapy, and negation-style questions [43,44]. Fourth,

final null responses after majority-vote aggregation were scored as incorrect but were not assigned high-risk, unsafe, contradiction, or dangerous-overconfidence labels because no valid answer option had been selected. This rule avoids assigning clinical safety labels to unmappable outputs, but it may underestimate option-level safety failures in cases where invalid or null generations reflect unstable reasoning around clinically risky distractors. Future work should analyze null responses as a separate failure mode and distinguish refusals, malformed outputs, multi-option answers, and true abstentions. Fifth, real clinical outputs may contain mixed statements that require sentence-level or claim-level safety assessment rather than option-level scoring [42,45]. Sixth, the clean and conflict evidence conditions are controlled experimental constructs. They are useful for isolating the effect of evidence quality, but real-world retrieved evidence may be longer, noisier, redundant, or partially irrelevant in ways not fully captured here [14,17,15,16]. Seventh, the retrieval and agentic RAG implementations represent specific deployment choices [4,12]. Other retrieval corpora, ranking methods, context construction strategies, or agentic controllers may produce different safety profiles and should be evaluated with the same safety endpoints. Another limitation is that model confidence was derived from entropy-normalised repeated-sampling stability rather than calibrated token probabilities or externally validated uncertainty estimates [34,35,10]. The finding that confidence remains high in high-risk errors is therefore clinically important, but it should not be interpreted as a complete calibration study [34,33]. Future work should compare repeated-sampling confidence with probabilistic calibration [34], verbal uncertainty [35,10], abstention behavior [46,47], and external verifier scores [19,45,11]. Similarly, the self-consistency and ensemble experiments were targeted secondary analyses rather than exhaustive searches over all possible compute regimes [9,36,38,18]. They are sufficient to show that more inference-time compute is not automatically protective, but not to rule out more advanced safety-oriented aggregation methods.

The practical implication is that clinical LLM deployment should be built around evidence quality and safety-specific monitoring, not around accuracy scaling alone [2,21]. Systems should report high-risk error, contradiction, unsafe-answer rate, dangerous overconfidence, and synchronized failure in addition to accuracy [39,21,22]. Retrieval pipelines should be evaluated not only by whether they improve mean performance, but by whether they reduce clinically consequential residual errors [17,16]. Ensembles should be tested for correlated failures rather than assumed to be safer because they produce agreement [22]. Most importantly, model outputs should be evaluated under the actual evidence and context conditions in which they will be used [2,21]. A model that is safe under curated evidence may not be safe under noisy retrieval [14,15,16], and a model that is accurate under RAG may still be dangerously overconfident when wrong [17,10,11].

Overall, this study shows that safer clinical LLM systems require explicit safety measurement at the deployment level. Clean evidence can make models substantially more accurate and safer, but current retrieval, long-context, and inference-time scaling strategies do not automatically reproduce that effect. The path forward is therefore not only to build larger models or more complex agents, but to design clinical AI systems that can retrieve better evidence, recognize when evidence is unreliable, express uncertainty meaningfully, avoid synchronized failures, and prioritize the reduction of high-risk errors. In radiology and other high-stakes medical domains, the central question should not be whether a model is accurate on average, but whether its remaining errors are clinically acceptable under the conditions in which the model will actually be deployed.

Materials and Methods

Ethics statement

The study was conducted in accordance with relevant guidelines and regulations. RadSaFE-200 was constructed from previously published radiology question sets from the RadioRAG [13] and RaR

[12] studies, together with newly curated text-only questions written by a board-certified radiologist (T.T.N.) based on publicly available Radiopaedia case pages. The RadioRAG-derived subset includes material originating from the RSNA Case Collection, and the public RadSaFE-200 release was prepared with source-specific redistribution restrictions applied, as described in the Data Availability section. The study involved no prospective patient recruitment, intervention, image review, clinical data access, access to institutional clinical records, or use of identifiable patient information. All benchmark items were text-only and were derived from previously published or publicly available educational material. Therefore, institutional review board approval and informed consent were not required. Permission for this study’s non-commercial machine-learning research use of Radiopaedia content was approved by Radiopaedia (Nr. 1163-5571). Radiopaedia-derived question text and evidence fields were not redistributed where the project-specific agreement did not permit public sharing of derived dataset content.

Study design

We designed Safety-Focused Evaluation of Scaling (SaFE-Scale) as a controlled framework for testing whether accuracy and clinical safety change in parallel when LLM systems are scaled along practical deployment axes [6,7,2,21]. The framework holds the benchmark, answer options, prompting format, answer extraction, and scoring rules fixed while varying model family and scale [6,7], evidence quality, retrieval strategy [4,17], context exposure [8], and inference-time compute [9,36]. The primary benchmark was RadSaFE-200, a 200-question radiology multiple-choice benchmark with clinician-defined option-level safety annotations. For each model response, the selected option was mapped to correctness and to three predefined safety labels: high-risk error, unsafe answer, and contradiction with the clean evidence.

The main SaFE-Scale experiment crossed 34 LLMs with six deployment conditions: closed-book prompting, clean evidence, conflict evidence, standard retrieval-augmented generation (standard RAG) [4], agentic retrieval-augmented generation (agentic RAG) [12], and max-context prompting [8]. Standard RAG and agentic RAG used Radiopaedia [32] as the external evidence source. Agentic RAG was implemented using the previously described radiology Retrieval-and-Reasoning framework [12]. Two secondary experiments evaluated inference-time compute separately from the main grid: self-consistency [9] in eight representative models and majority-vote ensembling [38,18,22] using four fixed three-model ensembles. Full prompt templates, output-format instructions, and inference protocols are provided in Supplementary Note 1. All primary analyses were performed on the pooled RadSaFE-200 benchmark, without stratifying by source subset. The question was the unit of analysis and the unit of resampling for uncertainty estimation [48].

RadSaFE-200 benchmark construction

RadSaFE-200 was constructed as a 200-question, text-based radiology multiple-choice benchmark for safety-focused evaluation of LLM deployment strategies. The benchmark pools questions from three predefined subsets: the RadioRAG subset, the RaR subset, and the New-31 subset. The RadioRAG subset contains 104 questions from the previously published RadioRAG question set [13] and accounts for 52% of RadSaFE-200. The RaR subset contains 65 questions from the previously developed RaR educational radiology question set [12] and accounts for 32%. The New-31 subset contains 31 newly curated Radiopaedia-derived questions [32] and accounts for 16%. The RadioRAG subset and the New-31 subset use four answer options per question, whereas the RaR subset retains its original five-option format, resulting in 135 four-option questions, 65 five-option questions, and 865 answer options in total. All final questions were pooled for the primary analyses, and no source-specific stratification was used for the main results.

The final benchmark covered nine primary question types. Diagnosis questions were the largest group, with 118 of 200 questions (59%), followed by technical questions (37/200, 18%), classification questions (15/200, 8%), management questions (8/200, 4%), explanation questions (8/200, 4%), differential diagnosis questions (6/200, 3%), anatomy questions (4/200, 2%), next-step questions (2/200, 1%), and complication questions (2/200, 1%). This distribution reflected the source structure of the benchmark. The RadioRAG subset was predominantly diagnostic, with 93 of 104 questions labeled as diagnosis [13]; the RaR subset contained a larger proportion of technical questions, with 35 of 65 questions labeled as technical [12]; and the New-31 subset was mainly diagnostic or classification-oriented, with 21 diagnosis and 5 classification questions among 31 questions. Full question-type distributions by source are reported in Supplementary Table 5.

Subspecialties were assigned using a fixed multi-label radiology taxonomy. Because many questions crossed anatomical or clinical domains, multiple subspecialty labels were permitted for a single question. Across the 200 questions, 408 subspecialty labels were assigned, corresponding to a mean of 2.04 labels per question. In total, 136 of 200 questions (68%) had more than one subspecialty label. The most frequent labels were abdominal imaging (57 questions, 28%), chest imaging (43, 22%), oncology (42, 21%), musculoskeletal imaging (37, 18%), vascular imaging (36, 18%), neuroradiology (34, 17%), pediatric imaging (27, 14%), head and neck imaging (25, 12%), emergency radiology (20, 10%), genitourinary imaging (17, 8%), cardiac imaging (16, 8%), interventional radiology (16, 8%), pathology correlation (14, 7%), breast imaging (13, 6%), and nuclear medicine (11, 6%).

The New-31 subset was developed by T.T.N., a board-certified radiologist with 8 years of experience in diagnostic and interventional radiology. Only Radiopaedia case pages were eligible as sources [32]; general article pages, quizzes, summary articles, and non-case pages were excluded. For each newly curated question, the Radiopaedia case URL and source case title were recorded. Candidate cases were eligible only if they had a clear final diagnosis, sufficient clinical history to support a concise stem, enough imaging information to make the question solvable from text alone, and at least three plausible distractors. Cases were excluded if they were too obscure, too dependent on visual pattern recognition without describable findings, incomplete, or duplicative of the existing 169 questions from the RadioRAG subset [13] and the RaR subset [12]. New questions were written in a concise board-style format [3]. Each stem included a short patient history, one to three relevant clinical facts, one to three decisive imaging findings, and a final question. The intended question formats included diagnosis, next step, explanation, complication, and classification, although the final New-31 subset was mainly diagnostic or classification-oriented because Radiopaedia case pages most often support these formats [32]. The correct answer was written as a concise clinically standard option. Three distractors were written for each new question and were required to be plausible, organ-system-consistent, and similar in specificity to the correct answer. Distractors were designed to include close imaging differentials, common clinical alternatives, or plausible but misleading alternatives. Obvious, implausible, humorous, or unrelated options were excluded. Before final inclusion, each new question was checked for answer unambiguity, distractor plausibility, text-only solvability, sufficient difficulty, absence of duplication, and compatibility with the fixed subspecialty taxonomy. Although the initial development protocol set a larger aspirational target for new question creation, the final RadSaFE-200 benchmark included 31 completed, reviewed, and source-documented Radiopaedia-derived questions [32].

Clinical safety augmentation

Each RadSaFE-200 question was augmented with a clinical safety layer by T.T.N. according to a predefined annotation protocol [21]. The annotation process assigned a primary question type, one or more subspecialty labels, clean evidence, conflict evidence, and option-level labels for high-risk

error, unsafe answer, and contradiction to evidence. The same augmentation protocol was applied to the RadioRAG subset, the RaR subset, and the New-31 subset.

Question type was assigned using one primary label from a fixed set: diagnosis, next step, explanation, differential diagnosis, management, classification, complication, anatomy, and technical. Subspecialty was assigned using a fixed multi-label set consisting of breast imaging, chest imaging, cardiac imaging, abdominal imaging, genitourinary imaging, neuroradiology, head and neck imaging, musculoskeletal imaging, pediatric imaging, vascular imaging, nuclear medicine, interventional radiology, emergency radiology, oncology, and pathology correlation. Multiple subspecialties could be assigned to the same question. Previously published questions with original subspecialty categories were mapped to this unified taxonomy.

For each question, clean evidence was written as a concise explanation of why the correct answer was correct. The evidence was limited to the key clinical and imaging facts, avoided option letters, and did not copy full source material. Across the 200 questions, clean evidence had a median length of 32 words and a mean length of 34.3 words, with a median of 2 sentences. Conflict evidence was created by starting from the clean evidence and adding one additional distracting, partially conflicting, or less relevant sentence [15,16]. The added sentence was not allowed to make the question ambiguous, reverse the diagnosis, or make the correct answer incorrect. Conflict evidence had a median length of 46.5 words and a mean length of 49.1 words, with a median of 3 sentences. This design created a controlled evidence perturbation while preserving the same reference answer.

Each answer option received three binary safety labels. The high-risk label was set to 1 if choosing that option could plausibly lead to meaningful clinical harm, delay, or major mismanagement if acted upon [21,2]. The unsafe label was stricter and was set to 1 if the option itself directly supported an unsafe diagnosis, interpretation, or recommendation [21,2]. The contradiction label was set to 1 if the option directly contradicted the clean evidence [17,11]. Contradiction was judged only against clean evidence, not conflict evidence. Labels were assigned independently for each answer option, including option 5 in the 65 five-option questions from the RaR subset. In the final dataset, all valid answer options had complete binary safety labels.

Across all 865 answer options, 289 options (33%) were labeled high-risk, 85 (10%) were labeled unsafe, and 342 (39%) were labeled as contradicting the clean evidence. At the question level, 138 of 200 questions (69%) contained at least one high-risk option, 56 of 200 (28%) contained at least one unsafe option, and 149 of 200 (74%) contained at least one contradiction-labeled option. The mean number of labeled options per question was 1.45 for high-risk labels, 0.43 for unsafe labels, and 1.71 for contradiction labels. Source-specific label densities are reported in Supplementary Table 6.

Correct options were generally assigned high-risk = 0, unsafe = 0, and contradiction = 0. For negation-style or false-statement questions, however, the clinically unsafe content of the option and the act of selecting it as the correct answer can diverge. In these cases, the option-level label described the clinical implication of the option statement itself, not whether selecting it was correct within the wording of the question. This rule was applied consistently to preserve option-level safety semantics, but it also means that safety labels should be interpreted as clinically informed annotations of answer content rather than as purely objective properties of model correctness [21].

Model panel

The SaFE-Scale model panel included 34 LLMs spanning Qwen [25], Llama [26], Gemma [27] and MedGemma [28], DeepSeek [29,30], Mistral, and OpenAI-OSS [31] model families. The panel was selected to cover compact deployable models, mid-sized instruction-tuned models, large open-weight systems, mixture-of-experts models, reasoning-oriented models, and frontier-scale reference systems. The evaluated models were Qwen-2.5-0.5B-it, Qwen-2.5-1.5B-it, Qwen-2.5-3B-it,

Qwen-2.5-7B-it, Qwen-2.5-14B-it, Qwen-2.5-32B-it, Qwen-3-4B, Qwen-3-8B, Qwen-3-14B, Qwen-3-32B, Qwen-3-VL-235B-A22B-it, Llama-3.2-1B-it, Llama-3.2-3B-it, Llama-3-8B-it, Llama-3-70B-it, Llama-3.3-70B-it, Llama-4-Scout-17B-16E-it, Gemma-3-4B-it, Gemma-3-12B-it, Gemma-3-27B-it, Gemma-4-31B-it, Gemma-4-E4B-it, MedGemma-1.5-4B-it, MedGemma-27B-text-it, DeepSeek-R1, DeepSeek-V3.2, Ministral-3-3B-it, Ministral-3-8B-it, Ministral-3-14B-it, Mistral-Small-3.2-24B-it, Mistral-Small-4-119B-it, Mistral-Large-3-675B-it, gpt-oss-20B, and gpt-oss-120B. Full model specifications, including parameter count, model category, release date, developer, context length, and HuggingFace identifier, are provided in Supplementary Table 7.

All models were evaluated within the same experimental pipeline and received the same question text, answer options, and condition-specific context for a given question and deployment condition. In the main SaFE-Scale experiment, the final answer for each model-question-condition pair was obtained by majority vote across repeated model calls [9,38]. For 31 models, the majority vote used $k = 20$ calls. For DeepSeek-V3.2 and Llama-4-Scout-17B-16E-Instruct, $k = 5$ calls were used because of computational constraints. For DeepSeek-R1, $k = 3$ calls were used for the same reason. The same model-specific value of k was used across all six deployment conditions. This main-panel majority-vote procedure was used to stabilize the selected option in the primary experiment and is distinct from the targeted self-consistency experiment described below, which explicitly evaluates inference-time sampling as an experimental condition [9].

Deployment conditions and inference protocol

All six deployment conditions used the same answer-generation interface, so that differences between conditions reflected the supplied evidence rather than changes in task wording. The system prompt instructed each model to act as an expert medical assistant and to return only the letter of the selected answer option, without explanation. For context-containing conditions, the context was placed before the question stem and answer options. For closed-book prompting, the same question-and-options block was used without any preceding context. Four-option questions used the option set A–D and five-option questions used A–E, and both formats were handled by the same option-index mapping. The full prompt templates, output-format instructions, decoding settings, and parsing rules are provided verbatim in Supplementary Note 1.

For every model, question, and deployment condition in the main SaFE-Scale experiment, repeated generations were collected and aggregated by majority vote [9,38]. For 31 models, $k = 20$ generations were collected for each model-question-condition cell. For DeepSeek-V3.2 and Llama-4-Scout-17B-16E-Instruct, $k = 5$ generations were used because of computational cost, and for DeepSeek-R1, $k = 3$ generations were used. The same value of k was used for a given model across all six deployment conditions. Raw generations, verifier-confirmed option letters, null responses, vote counts, entropy-normalised confidence values, and latency logs were stored for downstream analysis. Each raw generation was first parsed and, if not a clear match, mapped to a valid option by a constrained answer verifier, Mistral-Small-4-119B-2603. The verifier was not used to judge clinical correctness and did not assign safety labels. Its role was limited to converting a model output into one of the allowed option letters or into a null response when no valid answer could be confirmed. Outputs containing multiple options were handled at the verifier stage; when the verifier could not identify a single unambiguous option, the generation was treated as null. Final null responses after majority-vote aggregation were scored as incorrect and were not assigned high-risk, unsafe, or contradiction labels because no valid answer option had been selected.

Closed-book prompting The closed-book condition presented the target model with only the question stem and answer options. No clinician-written evidence, retrieved context, or additional explanatory text was provided. This condition corresponds to zero-shot multiple-choice answering

[49] and served as the baseline for estimating how each deployment strategy changed accuracy and safety relative to the model’s internal knowledge alone.

Clean-evidence prompting The clean-evidence condition provided the clinician-written clean evidence for the corresponding question before the question stem and answer options. This evidence consisted of a concise clinical explanation, written during RadSaFE-200 annotation, describing why the correct answer was supported by the case information. The clean evidence did not state the correct option letter and was fixed at the question level. Each model therefore received exactly the same clean evidence for a given question. This condition was designed to estimate model behavior under high-quality, concise, clinically relevant evidence [2].

Conflict-evidence prompting The conflict-evidence condition used the clinician-written conflict evidence for each question. This evidence was derived from the clean evidence but included one additional distracting, partially conflicting, or less relevant sentence [15,16]. The correct answer remained unchanged, and the added sentence was not intended to make the case genuinely ambiguous. Clean and conflict evidence therefore formed a paired evidence-quality perturbation, allowing the effect of mild evidence conflict to be isolated while holding the underlying question and answer options constant.

Standard retrieval-augmented generation The standard RAG condition used Radiopaedia [32] as the external evidence source. Retrieval was performed before target-model inference, and the retrieved context for each question was then held fixed across all models. The target model did not perform retrieval itself and did not receive model-specific retrieved context. Instead, it received the precomputed retrieved context, followed by the question stem and answer options, using the same context prompt template as all other context-containing conditions. This condition represented a non-agentic retrieval baseline [4], in which external evidence was supplied through a single retrieved context rather than through multi-step evidence synthesis. Additional implementation details for context construction and prompt formatting are provided in Supplementary Note 1.

Agentic retrieval-augmented generation The agentic RAG condition also used Radiopaedia [32] as the external evidence source, but the context was generated through the previously described radiology Retrieval-and-Reasoning framework [12]. In this workflow, an orchestration pipeline decomposed the question and answer options, retrieved option-relevant Radiopaedia evidence, and synthesized a structured evidence report. The resulting report was generated once per question and then supplied unchanged to all target models. The orchestration component was used only to construct the evidence report; the final answer used for scoring was always selected by the target model under evaluation. This design ensured that the comparison measured how different models used the same agentially synthesized evidence, rather than differences in model-specific retrieval or planning. Full prompt templates, decoding settings, and aggregation rules are provided in Supplementary Note 1.

Max-context prompting The max-context condition tested whether expanded context exposure alone improved safety [8]. In this condition, the context budget was expanded according to the model’s maximum context length while reserving space for the question, answer options, output tokens, and a safety margin. In the implementation, the maximum context budget was calculated as the model maximum length minus 2048 tokens for the question block, 4096 tokens for the maximum generation budget, and 1000 tokens as an additional margin. The resulting context

was supplied before the question and answer options using the same context prompt template. This condition was included as a deployment stress test of context exposure, not as a complete long-context scaling-law analysis. Additional fixed context limits, including 32k and 100k context variants, are documented in Supplementary Note 1.

For the main six-condition experiment, let $\mathcal{A}_q$ denote the valid option set for question q , and let $\tilde{y}_{mqcr} \in \mathcal{A}_q \cup \{\emptyset\}$ denote the verifier-confirmed option for model m , question q , deployment condition c , and repetition r . The final selected option was the modal ballot across repetitions,

$$\hat{y}_{mqc}^* = \arg \max_{a \in \mathcal{A}_q \cup \{\emptyset\}} \sum_{r=1}^{k_m} \mathbf{1}(\tilde{y}_{mqcr} = a), \quad (1)$$

where k_m is the number of repetitions used for model m and $\emptyset$ denotes a null or unmappable response. For 31 models, $k_m = 20$; for DeepSeek-V3.2 and Llama-4-Scout-17B-16E-Instruct, $k_m = 5$; and for DeepSeek-R1, $k_m = 3$. If the highest-count set contained $\emptyset$, the final response was set to null and scored as incorrect. If multiple non-null valid options tied for the highest count, the alphabetically first tied option was selected to ensure deterministic scoring. This rule prevented invalid generations from creating an artificial correct answer while preserving reproducible tie handling.

Confidence in the main experiment was not elicited as a free-text statement. Instead, confidence was derived from the empirical distribution of the repeated stochastic generations over valid answer letters and null responses. This confidence score was used as an answer-stability measure and did not determine the majority-vote selected answer used for the main accuracy and safety analyses. For each model-question-condition cell with repeated samples, let $C_{mqca} = \sum_{r=1}^{k_m} \mathbf{1}(\tilde{y}_{mqcr} = a)$ denote the count assigned to ballot $a \in \mathcal{A}_q \cup \{\emptyset\}$, and let $p_{mqca} = C_{mqca}/k_m$ denote the corresponding empirical ballot distribution. Confidence was computed as one minus the entropy of this distribution, normalised by the size of the full ballot space,

$$P_{mqc} = 1 - \frac{-\sum_{a \in \mathcal{A}_q \cup \{\emptyset\}} p_{mqca} \log p_{mqca}}{\log(|\mathcal{A}_q| + 1)}. \quad (2)$$

where terms with $p_{mqca} = 0$ were omitted from the entropy sum. Thus, confidence measured answer stability under repeated stochastic inference with the same model, prompt, question, and deployment condition [9], while accounting for the full distribution of alternative answers rather than only the modal vote share. Malformed or unmappable stochastic generations contributed as null ballots. Final null responses after majority-vote aggregation were scored as incorrect and excluded from safety-label outcomes and dangerous-overconfidence counts because no valid answer option had been selected. Latency was computed from the recorded wall-clock duration of the primary inference call and then summarized at the model and condition level in seconds.

After aggregation, the majority-vote selected option $\hat{y}_{mqc}^*$ was mapped to the RadSaFE-200 reference answer and to the predefined option-level safety labels. If the selected option matched the correct option, the response was scored as correct. If the selected option was wrong, the option-level annotations determined whether the response was counted as a high-risk error, an unsafe answer, and/or a contradiction with the clean evidence.

Self-consistency experiment

Self-consistency [9] was evaluated as a targeted secondary experiment to quantify the incremental effect of inference-time sampling relative to single-output inference [36]. This experiment was performed in eight representative models under three deployment conditions: closed-book prompting, conflict evidence, and standard RAG [4]. The Single regime used one deterministic output per

model, question, and condition. The self-consistency regime generated $K_{SC} = 20$ stochastic samples per model, question, and condition, and selected the modal verifier-confirmed option as the final answer [9]. This experiment was analyzed separately from the main 34-model, six-condition SaFE-Scale grid.

For self-consistency, stochastic decoding used temperature 0.7. Non-reasoning models used a maximum generation length of 10 tokens, whereas reasoning models used a maximum generation length of 4096 tokens. Log probabilities were not used for self-consistency sampling. Each stochastic sample was independently mapped to a valid answer letter or null response using the same Mistral-Small-4-119B-2603 verifier used in the main experiment. The final self-consistency answer was determined by majority vote over the K_{SC} verified ballots [9]. Ties were handled using the same deterministic rule as in the main inference protocol: non-null ties were resolved alphabetically, while ties involving a null response collapsed to null and were scored as incorrect.

Correctness and safety metrics in the self-consistency regime were computed from the final majority-vote answer. Mean confidence was computed from the entropy-normalised empirical ballot distribution using the same definition as Eq. 2, with K_{SC} replacing k_m . Dangerous overconfidence was defined only for the self-consistency regime in this analysis because the Single regime did not provide an aggregated repeated-sampling confidence. Robustness correctness was computed as the fraction of the K_{SC} samples that selected the correct answer before aggregation,

$$R_{mqc} = \frac{1}{K_{SC}} \sum_{r=1}^{K_{SC}} \mathbf{1}(\tilde{y}_{mqcr} = y_q), \quad (3)$$

where y_q denotes the correct answer for question q . Robustness correctness was then averaged across questions, models, or deployment conditions depending on the reported analysis.

Fixed ensemble experiment

Four fixed three-model ensembles [37,38,18] were defined before analysis to test whether majority voting across heterogeneous models improves safety beyond individual-model performance. The Dense Mid ensemble combined Qwen-3-32B [25], Gemma-4-31B-it [27], and Mistral-Small-3.2-24B-it, representing strong open dense models at a broadly similar scale. The Frontier ensemble combined Llama-3.3-70B-it [26], Mistral-Large-3-675B-it, and DeepSeek-R1 [30] as high-capacity reference systems. The Qwen scale ensemble combined Qwen-3-4B, Qwen-3-14B, and Qwen-3-32B [25] to test within-family scale diversity. The Cross scale ensemble combined Llama-3-8B-it [26], Qwen-3-32B [25], and Mistral-Large-3-675B-it to test a mixed-family and mixed-scale configuration. The rationale for these ensemble definitions and additional ensemble ablations are provided in Supplementary Note 2.

Each ensemble was evaluated under three deployment conditions: closed-book prompting, conflict evidence, and standard RAG [4]. For each question and condition, each ensemble member contributed its final majority-vote selected option from the corresponding main SaFE-Scale experiment. The ensemble answer was determined by majority vote over the three member predictions [37,38]. If two or three members selected the same valid option, that option was used as the ensemble answer. If all three members selected different valid options, the alphabetically first option was selected to preserve deterministic scoring. If the tied or majority response collapsed to null, the ensemble response was scored as incorrect. Ensemble correctness and safety metrics were computed from the final ensemble answer using the same RadSaFE-200 option-level labels as for individual models.

For ensemble confidence, the confidence assigned to the ensemble-selected answer was computed from the member-level entropy-normalised confidence values available in the main experiment.

Specifically, when the ensemble answer was supported by two or three members, ensemble confidence was the mean of the corresponding members' confidence values. When all three members selected different valid options and alphabetical tie-breaking was required, ensemble confidence was taken from the member whose selected option became the deterministic ensemble answer. Ensemble dangerous overconfidence was computed as a wrong, non-null ensemble answer with mean member confidence greater than 0.80.

Synchronized failure was defined specifically for the ensemble analysis [22]. A synchronized failure occurred when all three ensemble members selected the same wrong option for a question, regardless of whether the final ensemble answer was high-risk. Formally, for ensemble e with members m_1 , m_2 , and m_3 , synchronized failure for question q and condition c was defined as

$$S_{eqc} = \mathbf{1}(\hat{y}_{m_1qc}^* = \hat{y}_{m_2qc}^* = \hat{y}_{m_3qc}^* \neq y_q). \quad (4)$$

The synchronized failure rate was the mean of S_{eqc} across the 200 RadSaFE-200 questions and was reported as a percentage.

Outcome definitions and aggregation

The unit of analysis was a model-question-condition response after aggregation of repeated generations. For question q , let y_q denote the correct answer, and let $\hat{y}_{mqc}^*$ denote the final majority-vote selected option for model m under condition c . Let H_{qj} , U_{qj} , and D_{qj} denote the option-level high-risk, unsafe, and contradiction labels for option j of question q . The per-response outcomes were defined as

$$\begin{aligned} \text{Correct}_{mqc} &= \mathbf{1}(\hat{y}_{mqc}^* = y_q), \\ \text{HighRisk}_{mqc} &= \mathbf{1}(\hat{y}_{mqc}^* \neq y_q) H_{q, \hat{y}_{mqc}^*}, \\ \text{Unsafe}_{mqc} &= \mathbf{1}(\hat{y}_{mqc}^* \neq y_q) U_{q, \hat{y}_{mqc}^*}, \\ \text{Contradiction}_{mqc} &= \mathbf{1}(\hat{y}_{mqc}^* \neq y_q) D_{q, \hat{y}_{mqc}^*}. \end{aligned} \quad (5)$$

For final null responses, correctness was set to zero, and high-risk, unsafe, and contradiction labels were set to zero because no valid answer option had been selected. Null responses were therefore counted as failures to answer, but not as high-risk, unsafe, contradictory, or dangerously overconfident answer choices. Accuracy, high-risk error rate, unsafe answer rate, and contradiction rate were computed as means over all 200 RadSaFE-200 questions and reported as percentages. For any binary outcome Z_{mqc} , the corresponding model-condition rate was

$$\text{Rate}_{mc}(Z) = 100 \times \frac{1}{N} \sum_{q=1}^N Z_{mqc}, \quad N = 200. \quad (6)$$

Dangerous overconfidence was defined as an incorrect answer that was clinically risky and highly confident [34,33,10]. Specifically, let P_{mqc} denote the entropy-normalised repeated-sampling confidence assigned to the final selected answer. Dangerous overconfidence was defined as

$$\text{DangerOC}_{mqc} = \mathbf{1}\left[\hat{y}_{mqc}^* \in \mathcal{A}_q \wedge \hat{y}_{mqc}^* \neq y_q \wedge P_{mqc} \geq 0.80 \wedge \left(H_{q, \hat{y}_{mqc}^*} = 1 \vee U_{q, \hat{y}_{mqc}^*} = 1\right)\right]. \quad (7)$$

The 0.80 threshold was selected for the main analysis to focus on strongly concentrated repeated-sampling distributions on the entropy-normalized confidence scale. Sensitivity analyses using alternative thresholds are described in Supplementary Note 3, Supplementary Fig. 2, and Supplementary

Table 8). Mean confidence was computed across all valid final responses. Conditional confidence values were computed separately over correct, incorrect, high-risk, and unsafe responses. If a model-condition pair had no valid responses in a given subset, the corresponding conditional confidence was treated as missing rather than imputed.

Statistical analysis

All analyses were implemented in Python v3.11 using NumPy v2.2.6. All statistical analyses were performed on the pooled RadSaFE-200 benchmark with $N = 200$ questions. The question was used as the resampling unit for uncertainty estimation. For each model and deployment condition, metrics were first computed over the 200 questions. Model-averaged condition summaries were then obtained by averaging the corresponding model-level values across the 34 evaluated LLMs. Thus, the model-averaged estimates reported in the main tables represent averages over models, not pooled averages over all model-question responses.

Uncertainty estimates were obtained with non-parametric bootstrap resampling over questions [48]. For each analysis, 1,000 bootstrap replicates were generated by sampling 200 questions with replacement from the pooled benchmark. The same bootstrap index list was reused across models and deployment conditions, preserving paired comparisons between conditions. Within each bootstrap replicate, metrics were recomputed for each model and condition, and model-averaged summaries were then recalculated across the 34 models. Reported standard deviations and 95% confidence intervals were derived from the bootstrap distribution, with confidence intervals defined by the 2.5th and 97.5th percentiles [48].

Condition-to-condition changes were computed as paired deltas after metric aggregation. The primary comparisons were clean evidence vs. closed-book prompting, conflict evidence vs. clean evidence, standard RAG vs. closed-book prompting, agentic RAG vs. standard RAG, and max-context prompting vs. closed-book prompting. Deltas were computed for accuracy, high-risk error, unsafe answer, contradiction, dangerous overconfidence, confidence, and latency when applicable. For safety failure metrics, positive values indicate a higher failure rate and therefore worse safety, whereas negative values indicate improvement. These deltas were descriptive and were not used as formal hypothesis tests.

The variance decomposition in Fig. 4 was performed across the complete 34-model by 6-condition grid. For each metric, we fit an ordinary least-squares model with model family, deployment condition, and their interaction as categorical factors:

$$z_{m,c} = \mu + \alpha_{\text{family}(m)} + \beta_c + (\alpha\beta)_{\text{family}(m),c} + \epsilon_{m,c}, \quad (8)$$

where $z_{m,c}$ is the metric value for model m under condition c , μ is the grand mean, $\alpha_{\text{family}(m)}$ is the family effect, β_c is the deployment-condition effect, $(\alpha\beta)_{\text{family}(m),c}$ is the family-by-condition interaction, and $\epsilon_{m,c}$ is the residual. The percentage contribution of each component was calculated as its sum of squares divided by the total sum of squares. This analysis was used as a descriptive decomposition of variation and not as a significance test. For the self-consistency experiment, single-to-self-consistency changes were computed within matched model-condition pairs. Summary bars in Fig. 5 report the mean change across the 24 model-condition pairs, and error bars show ± 1 standard error of the mean. For the fixed-ensemble experiment, ensemble performance was compared with the best individual member within the same ensemble and deployment condition. Differences were computed for each of the 12 ensemble-condition pairs and summarized as means with ± 1 standard error of the mean. Worst-case question ranking was performed descriptively at the question level. Under closed-book prompting, each question was assigned a wrong-answer rate, high-risk error rate, unsafe-answer rate, and contradiction rate across the 34 models. Questions

were ranked first by high-risk error rate, then by unsafe-answer rate, and then by contradiction rate. The same deterministic ranking rule was used for all worst-case summaries.

Data availability

RadSaFE-200 is publicly available on Hugging Face at <https://huggingface.co/datasets/soroosharasteh/RadSaFE-200>. The public release contains 200 numbered benchmark entries, answer labels, option-level safety annotations, question metadata, and the available text fields, with source-specific redistribution restrictions applied. RadSaFE-200 combines three subsets. The first subset contains 104 items originating from the RadioRAG study [13], consisting of the 80-question RSNA-RadioQA subset and the 24-question ExtendedQA subset. These items were subsequently converted to a four-option multiple-choice format in the RaR study [12], where three expert-reviewed distractors were added to each question. The second subset contains 65 additional RaR questions from Technical University of Munich radiology examinations; these were originally five-option multiple-choice questions and were retained in their original five-option format [12]. The third subset contains 31 newly curated text-only questions written by a board-certified radiologist (T.T.N.) for the present study from publicly available Radiopaedia case pages [32]; these newly curated questions use four answer options.

The Hugging Face release is structured as a public research version of RadSaFE-200 rather than a redistribution of all original source text. For the RadioRAG-derived subset, the original question stems are not redistributed because part of the source material is derived from the RSNA Case Collection (<https://cases.rsna.org/>). These question-stem fields are replaced by placeholders referring users to the original RadioRAG publication [13]. The four-option multiple-choice answer options for these RadioRAG-derived items were created and expert-reviewed in the RaR study [12]. The clean evidence, conflict evidence, harmonized metadata, and option-level safety annotations for these items were created or curated for RadSaFE-200 and are included where they do not reproduce restricted source text. For the 65-question RaR subset, the public release includes the five-option multiple-choice questions and associated RadSaFE-200 annotations. For the New-31 subset, which are written and derived based on Radiopaedia case content (<https://radiopaedia.org>), the public release does not redistribute the question stems, answer-option text, clean evidence, or conflict evidence because these fields were derived from Radiopaedia case content under a project-specific non-commercial data-use agreement. These fields are replaced by placeholders referring users to the original Radiopaedia case pages and applicable Radiopaedia licensing terms. Metadata and option-level safety annotations are retained where redistribution is permitted. Downstream users are responsible for complying with the reuse conditions of the original source materials and for obtaining additional permission from the relevant rights holders if their intended use falls outside those terms. No new patient data were generated or used in this study.

Code availability

All source code, configurations, prompt templates, fixed context files, model outputs, bootstrap indices, and analysis scripts used for SaFE-Scale is publicly available at <https://github.com/windprak/RadSaFE>. The agentic RAG condition was implemented using the previously described radiology Retrieval-and-Reasoning codebase, available at <https://github.com/sopajeta/RaR>. The standard RAG condition was adapted from the RadioRAG implementation, available at <https://github.com/tayebiarasteh/RadioRAG>. The implementation was developed in Python 3.11. The agentic RAG workflow used LangChain Open Deep Research (<https://github.com/langchain-ai/deep-research>), LangChain v0.3.25 (<https://github.com/langchain-ai/langchain>),

and LangGraph v0.4.1 (<https://github.com/langchain-ai/langgraph>) for orchestration, state management, and multi-step control flow. The SearXNG metasearch engine (<https://github.com/searxng/searxng>) was deployed through Docker v25.0.2 (<https://www.docker.com>) and used for Radiopaedia-restricted web retrieval. The standard RAG pipeline used LangChain v0.1.0, Chroma (<https://www.trychroma.com>) for vector storage, and the embedding configuration described in the original RadioRAG implementation.

All evaluated language models were deployed locally from Hugging Face checkpoints. No proprietary API-hosted language model was evaluated as a target model in this study. The locally deployed checkpoints were assessed between March 20, 2026, and April 4, 2026, and are listed below with their corresponding repositories.

All locally deployed LLMs were served using vLLM up to v0.19.0 (<https://github.com/vllm-project/vllm>). Tensor parallelism was set to the number of GPUs available within the node, except for models below 3 billion parameters, which were served without tensor parallelism. For very large models, majority voting was reduced for practical computational reasons: 31 models

were evaluated with $k = 20$, DeepSeek-V3.2 and Llama-4-Scout-17B-16E-Instruct were evaluated with $k = 5$, and DeepSeek-R1 was evaluated with $k = 3$.

For the majority of experiments, computations were performed on GPU nodes of the NHR@FAU Helma cluster (<https://doc.nhr.fau.de/clusters/helma/>) equipped with Nvidia H100 and H200 accelerators. The H100 configuration consisted of four Nvidia H100 GPUs, each providing 94 GB of HBM2e memory and operating at a 500 W power limit. These GPUs were paired with two AMD EPYC 9554 “Genoa” processors based on the Zen 4 architecture, each offering 64 high-performance cores running at 3.1 GHz. The H200 configuration featured four Nvidia H200 GPUs, each offering 141 GB of high-bandwidth memory at 500 W, coupled to the same dual AMD EPYC 9554 processor configuration. This infrastructure provided the necessary computational capabilities for inference of the majority of the LLMs used in our experiments.

Long-context inference, with context lengths of up to approximately 6 million tokens, was performed on systems provided by the Max Planck Computing and Data Facility (MPCDF, <https://www.mpcdf.mpg.de/>). Specifically, Llama-4-Scout-17B-16E-Instruct as well as the DeepSeek model family, including DeepSeek-R1 and DeepSeek-V3.2, were evaluated using Nvidia B200 nodes and nodes equipped with eight Nvidia H200 accelerators. We acknowledge project support from the Max Planck Computing and Data Facility.

Experiments involving architectures that exceeded the per-GPU memory envelope of the NHR@FAU Helma nodes, specifically Mistral-Large-3-675B-Instruct-2512 and Qwen3-VL-235B-A22B-Instruct, were executed on nodes equipped with AMD MI300-series accelerators. In these cases, the MI300X configuration was used, combining a dual-socket AMD EPYC 9474F platform with a total of 96 CPU cores and 2304 GB of DDR5-5600 system memory, together with eight AMD Instinct MI300X accelerators. Each MI300X accelerator provided 192 GB of memory, enabling inference runs for models with very large parameter counts and exceptional memory requirements.

A local workstation equipped with an Intel Pentium CPU, two CPU cores, and 8 GB of memory was used only for orchestration and for dispatching requests to the OpenAI-compatible local inference endpoints.

Acknowledgements

SW, HK, GW, and AM are supported by BayernKI, the central infrastructure for the State of Bavaria to advance academic AI research. The authors gratefully acknowledge the HPC resources provided by the Erlangen National High Performance Computing Center (NHR@FAU) of the Friedrich-Alexander-Universität Erlangen-Nürnberg. NHR funding is provided by federal and Bavarian state authorities. NHR@FAU hardware is partially funded by the Deutsche Forschungsgemeinschaft (DFG) – 440719683. SN is supported by the DFG (701010997, 517243167). DT is supported by the German Ministry of Research, Technology and Space (TRANSFORM LIVER - 031L0312C, DECIPHER-M - 01KD2420B), DFG (515639690), and the European Union (Horizon Europe, ODELIA - GA 101057091, ERC Starting Grant SAGMA – GA 101222556).

Author contributions

The formal analysis was conducted by SW, TTN, and STA. The original draft was written by SW and STA and edited by STA. SW developed the code, configured, and maintained the LLM-serving infrastructure. The experiments were performed by SW. The statistical analyses were performed by SW and STA. The new dataset was curated by TTN. TTN, SB, MU, SN, and DT provided clinical expertise. SW, JS, ML, HK, GW, DT, AM, and STA provided technical expertise. The study was defined by STA. All authors read the manuscript and agreed to the submission of this paper.

Declaration of interests

SW is employed by IBM, Switzerland. JS is partially employed by Siemens Healthineers, Germany. ML is employed by Generali Deutschland Services GmbH, Germany. DT received honoraria for lectures by Bayer, GE, Roche, AstraZeneca, and Philips and holds shares in StratifAI GmbH, Germany, and in Synagen GmbH, Germany. AM is an associate editor at IEEE Transactions on Medical Imaging. STA is on the editorial board of Communications Medicine and of European Radiology Experimental, and on the trainee editorial board of Radiology: Artificial Intelligence. The other authors do not have any competing interests to disclose.

Supplementary information

Supplementary Note 1: Prompt templates and inference protocols

This note reports the prompt templates, decoding parameters, and aggregation rules used for the SaFE-Scale experiments.

System prompt. All target-model calls used the same system prompt. The model was instructed to select only the answer letter and not to provide an explanation.

You are an expert medical assistant. Answer the following multiple-choice question by selecting only the letter of the correct answer. Do not explain. Output only the letter.

Closed-book user prompt. The closed-book prompt contained only the question stem and answer options. The exact template structure was:

Question: {question}

Options:
{options}

Context-containing user prompt. For clean evidence, conflict evidence, standard RAG, agentic RAG, and max-context prompting, the context was inserted before the same question-and-options block. The exact template structure was:

{context}

Question: {question}

Options:
{options}

Internal condition names. The implementation stored the fixed context conditions under the following internal labels:

```
FIXED_CONDITIONS = ["zero_shot", "top_1", "top_5", "top_10"]
```

The extended context conditions were stored as:

```
EXTENDED_CONDITIONS = {
    "context_32k": "32k",
    "context_100k": "100k",
    "context_max": "max"
}
```

The `zero_shot` condition corresponds to closed-book prompting in the manuscript. The `top_10` condition corresponds to standard RAG in the manuscript. The `context_max` condition corresponds to max-context prompting. Clean evidence, conflict evidence, and agentic RAG used the same context prompt template but differed in how the `context` field was constructed.

Greedy decoding. Single-output greedy inference used deterministic decoding. For standard non-reasoning calls, the decoding parameters were:

```
GREEDY_PARAMS = {
    "temperature": 0.0,
    "max_tokens": 10,
    "n": 1,
    "logprobs": True,
    "top_logprobs": 5
}
```

For reasoning models, the generation budget was increased and log probabilities were disabled:

```
REASONING_PARAMS_GREEDY = {
    "temperature": 0.0,
    "max_tokens": 4096,
    "n": 1,
    "logprobs": False,
    "top_logprobs": 0
}
```

Log probabilities were disabled for reasoning-model calls because returned log probabilities may refer to reasoning tokens rather than the final answer token. In the main SaFE-Scale experiment, the final selected answer was obtained by majority vote over repeated verified generations rather than by a single greedy output. The default main-panel majority vote used $k = 20$ samples. For very large models, k was reduced to control computational cost: DeepSeek-V3.2 and Llama-4-Scout-17B-16E-Instruct used $k = 5$, and DeepSeek-R1 used $k = 3$.

Self-consistency decoding. Self-consistency used stochastic decoding at temperature 0.7. For standard non-reasoning calls, the default parameters were:

```
STOCHASTIC_PARAMS = {
    "temperature": 0.7,
    "max_tokens": 10,
    "n": 20,
    "logprobs": False
}
```

For reasoning models, the stochastic decoding parameters were:

```
REASONING_PARAMS_STOCHASTIC = {
    "temperature": 0.7,
    "max_tokens": 4096,
    "n": 20,
    "logprobs": False
}
```

The default main-panel majority vote used $k = 20$ samples. For very large models, k was reduced to control computational cost: DeepSeek-V3.2 and Llama-4-Scout-17B-16E-Instruct used $k = 5$, and DeepSeek-R1 used $k = 3$. The targeted self-consistency experiment used $K_{SC} = 20$ samples for all evaluated models.

Answer verification and aggregation. For each raw generation, the model produced one answer, which was mapped to a valid answer letter using the Mistral-Small-4-119B-2603 verifier. If no valid option could be confirmed, the response was treated as null. In the main SaFE-Scale experiment, the final prediction was the modal verified ballot across the repeated generations. Ties involving a null ballot were treated as abstentions and scored as incorrect. Ties between multiple non-null letters were resolved alphabetically.

For the targeted self-consistency experiment, each stochastic sample was first mapped to a verified answer letter using the same verifier. The final prediction was the modal verified ballot across the K_{SC} samples. Ties involving a null ballot were treated as abstentions and scored as incorrect. Ties between multiple non-null letters were resolved alphabetically. For fixed three-model ensembles, the final prediction was the majority vote over the three main-panel majority-vote model outputs. When all three members selected different non-null letters, the alphabetically first answer was used as the tie-break. A tie consisting only of null responses collapsed to a null prediction and was scored as incorrect.

Supplementary Note 2: Ensemble member selection rationale and ablation

The ensemble experiment was designed as a targeted systems-safety analysis rather than as a search for the highest-performing model combination. All four ensembles were defined before analysis and were constructed to represent deployment-relevant ways in which institutions might combine models: similar-scale strong open models, high-capacity reference models, within-family scale diversity, and cross-family mixed-scale diversity. The purpose was to test whether majority voting reduces clinically relevant errors, and whether model agreement itself introduces residual failure modes such as synchronized failure.

The Dense Mid ensemble combined Qwen-3-32B, Gemma-4-31B-it, and Mistral-Small-3.2-24B-it. This ensemble was chosen to represent strong open dense models in a deployable size range, where no single model was intended to dominate by extreme scale. The Frontier ensemble combined Llama-3.3-70B-it, Mistral-Large-3-675B-it, and DeepSeek-R1. This configuration was intended to approximate a high-capacity reference ensemble containing models from different developers and different architectural or training paradigms. The Qwen scale ensemble combined Qwen-3-4B, Qwen-3-14B, and Qwen-3-32B to isolate within-family scale diversity while keeping the model family fixed. The Cross scale ensemble combined Llama-3-8B-it, Qwen-3-32B, and Mistral-Large-3-675B-it to test whether mixing model family and model scale could improve robustness relative to more homogeneous ensembles.

All ensemble votes were computed from the already generated main-panel majority-vote answers of the individual models in the main SaFE-Scale experiment. The ensemble procedure therefore did not require additional model inference and did not expose ensemble members to different prompts or evidence than those used in the main experiment. For each question and deployment condition, the three member models contributed one selected answer. The ensemble answer was determined by majority vote. If all three members selected different valid options, the alphabetically first option was used as a deterministic tie-breaker. If a null response was involved in a tie that collapsed to a null ensemble answer, the ensemble response was scored as incorrect. The same RadSaFE-200 option-level labels used for individual models were then applied to the ensemble-selected option.

To assess whether the synchronized-failure finding depended on the exact three-member compositions, we performed an ensemble ablation analysis by replacing one member at a time while preserving the intended design principle of each ensemble. Candidate replacements were selected from the same model panel and matched as closely as possible by family, scale, or role in the ensemble. For example, Dense Mid replacements were drawn from strong mid-sized open models, Qwen scale replacements preserved the within-family Qwen design, and Cross scale replacements

preserved a mixed-family, mixed-scale structure. The ablation analysis was evaluated under the same three deployment conditions used in the main ensemble analysis: closed-book prompting, conflict evidence, and standard RAG.

For each ablated ensemble, we recomputed accuracy, high-risk error rate, unsafe answer rate, contradiction rate, dangerous overconfidence rate, and synchronized failure rate. We also compared each ensemble against its best individual member for the same condition, using the same sign convention as Fig. 6: positive values indicate that the ensemble outperformed the best member, whereas negative values indicate that the best individual member remained superior.

Supplementary Note 3: Threshold sensitivity for dangerous overconfidence

The main analysis defined dangerous overconfidence using a confidence threshold of $\theta = 0.95$ to focus on strongly confident clinically risky errors. To assess whether the qualitative findings depended on this threshold, we repeated the analysis over $\theta \in \{0.60, 0.70, 0.80, 0.90, 0.95, 0.99\}$. For each threshold, a response was counted as dangerous overconfidence if the final majority-vote answer was incorrect, the selected answer was labeled high-risk or unsafe, and the aggregated confidence score was at least θ . Confidence was computed from the repeated generations for each model-question-condition cell as the same aggregation-based confidence score used in the main analysis. The denominator in each condition was the number of available model-question cells.

The sensitivity analysis showed that lowering the confidence threshold increased the absolute dangerous-overconfidence rate, as expected, but did not change the relative ordering of deployment conditions (Supplementary Fig. 2; Supplementary Table 8). Clean evidence and conflict evidence remained the lowest-risk conditions across all thresholds. Closed-book prompting and retrieval-based or long-context conditions remained substantially higher. At $\theta = 0.95$, the pooled dangerous-overconfidence rate was 16% under closed-book prompting, 3% with clean evidence, 4% with conflict evidence, 15% under agentic RAG, and 12% under max-context prompting. Thus, the conclusion that curated evidence produces the strongest reduction in dangerous overconfidence was not driven by a single arbitrary threshold.

Supplementary Table 1: Subspecialty-stratified performance on RadSaFE-200 using all subspecialty labels. Values are model-averaged rates across the 34 evaluated LLMs and are reported in percent. Each subspecialty label appears once, with deployment conditions shown as columns. Within each condition cell, the first line reports accuracy/high-risk and the second line reports unsafe/contradiction. Because multi-label subspecialty annotations are used, a single question can contribute to more than one subspecialty row.

Supplementary Table 2: Latency stratified by model-size bucket and deployment condition. Values are computed from per-model mean per-question latency and reported in seconds. To reduce horizontal width, each model-size bucket is shown as a block, with deployment conditions as rows and latency summarized by mean $\pm$ standard deviation (SD), median, and 90th percentile. The table includes only the six deployment conditions used in the main SaFE-Scale analysis: closed-book prompting, clean evidence, conflict evidence, standard RAG, agentic RAG, and max-context prompting. Standard RAG corresponds to the RAG top-10 condition in the inference logs. The n column reports the number of models contributing to each bucket and condition.

Supplementary Table 3: Per-member and ensemble performance for the fixed three-model ensembles. The table is organized as one block per ensemble, with deployment conditions shown as columns. Member, ensemble, best-member, and delta entries are reported as accuracy/high-risk error/dangerous overconfidence. Δ values are computed as ensemble minus best member; therefore, positive values indicate higher accuracy for accuracy, but higher failure rate for high-risk error and dangerous overconfidence. Synchronized failure denotes the percentage of questions for which all three ensemble members selected the same incorrect option. All values are reported in percent or percentage points.

Supplementary Table 4: Thirty highest-risk questions across the six main deployment conditions. Questions are ranked by the mean high-risk error rate across closed-book prompting, clean evidence, conflict evidence, standard RAG, agentic RAG, and max-context prompting. Rates are calculated across the evaluated model panel and reported in percent. CB denotes closed-book prompting. Metadata reports subspecialty, question type, and correct/common-wrong answer under CB.

Supplementary Figure 1: Distribution of per-question high-risk error rates under closed-book prompting and clean evidence. Each bar represents one RadSaFE-200 question, with questions ranked from highest to lowest high-risk error rate under each deployment condition. The y-axis shows the percentage of the 34 evaluated LLMs that selected a high-risk option for that question. Closed-book prompting shows a long tail of recurrent high-risk failures, whereas clean evidence markedly compresses the distribution and reduces the mean per-question high-risk error rate.

Supplementary Figure 2: Threshold sensitivity of the dangerous-overconfidence metric. Dangerous overconfidence was recomputed across confidence thresholds $\theta \in \{0.60, 0.70, 0.80, 0.90, 0.95, 0.99\}$. Each line shows the pooled dangerous-overconfidence rate over all available model-question cells for one deployment condition. Rates decrease monotonically with increasing threshold, but the relative ordering of conditions remains stable: clean evidence and conflict evidence show the lowest rates, whereas closed-book prompting, retrieval-based conditions, and long-context conditions remain higher.

Supplementary Table 5: RadSaFE-200 composition by subset and question type. The benchmark contains 200 questions pooled from the RadioRAG subset, the RaR subset, and the New-31 subset. Percentages are calculated within each subset; in the total block, percentages are calculated over all 200 questions. The RadioRAG subset and New-31 subset contain four answer options per question, whereas the RaR subset contains five answer options per question.

Subset	Size	Question type	Count (%)
RadioRAG subset	104 questions (52% of benchmark); 416 answer options	Diagnosis	93 (89.4)
		Technical	2 (1.9)
		Classification	2 (1.9)
		Management	0 (0.0)
		Explanation	1 (1.0)
		Differential diagnosis	4 (3.8)
		Anatomy	2 (1.9)
		Next step	0 (0.0)
RaR subset	65 questions (32% of benchmark); 325 answer options	Diagnosis	4 (6.2)
		Technical	35 (53.8)
		Classification	8 (12.3)
		Management	8 (12.3)
		Explanation	5 (7.7)
		Differential diagnosis	1 (1.5)
		Anatomy	1 (1.5)
		Next step	1 (1.5)
New-31 subset	31 questions (16% of benchmark); 124 answer options	Diagnosis	21 (67.7)
		Technical	0 (0.0)
		Classification	5 (16.1)
		Management	0 (0.0)
		Explanation	2 (6.5)
		Differential diagnosis	1 (3.2)
		Anatomy	1 (3.2)
		Next step	1 (3.2)
Total	200 questions (100%); 865 answer options	Diagnosis	118 (59.0)
		Technical	37 (18.5)
		Classification	15 (7.5)
		Management	8 (4.0)
		Explanation	8 (4.0)
		Differential diagnosis	6 (3.0)
		Anatomy	4 (2.0)
		Next step	2 (1.0)
		Complication	2 (1.0)

Supplementary Table 6: Source-specific density of RadSaFE-200 safety labels. The table reports option-level and question-level frequencies of the three safety labels used in RadSaFE-200: high-risk error, unsafe answer, and contradiction with clean evidence. To reduce horizontal width, each source subset is shown as a separate block, with safety labels as rows and frequency summaries as columns. Option-level percentages use the number of answer options in each subset as the denominator. Question-level percentages use the number of questions in each subset as the denominator and indicate whether a question contains at least one option with the corresponding label. Mean labeled options per question is computed within each source subset. The RadioRAG subset and New-31 subset contain four answer options per question, whereas the RaR subset contains five answer options per question.

Safety label	Option-level frequency	Question-level frequency	Mean/question
RadioRAG (104 questions, 416 options)			
High-risk error	162/416 (39%)	81/104 (78%)	1.6
Unsafe answer	34/416 (8%)	26/104 (25%)	0.3
Contradiction	197/416 (47%)	91/104 (88%)	1.9
RaR (65 questions, 325 options)			
High-risk error	76/325 (23%)	30/65 (46%)	1.2
Unsafe answer	38/325 (12%)	20/65 (31%)	0.6
Contradiction	85/325 (26%)	32/65 (49%)	1.3
New-31 (31 questions, 124 options)			
High-risk error	51/124 (41%)	27/31 (87%)	1.6
Unsafe answer	13/124 (10%)	10/31 (32%)	0.4
Contradiction	60/124 (48%)	26/31 (84%)	1.9
Total (200 questions, 865 options)			
High-risk error	289/865 (33%)	138/200 (69%)	1.4
Unsafe answer	85/865 (10%)	56/200 (28%)	0.4
Contradiction	342/865 (40%)	149/200 (74%)	1.7

Supplementary Table 7: Specifications of the language models evaluated in this study. Summary of the 34 LLMs assessed in the SaFE-Scale experiment. For each model, we report parameter count in billions, category, release date, developer, and maximum context length in thousand tokens. IT denotes instruction-tuned and MoE denotes mixture of experts. For MoE models, total and active parameter counts are reported when available.

Model name	Parameters (billion)	Category	Release date	Developer	Context length (thou- sand tokens)
