Abstract

The Observable Matrix Dynamics (OMD) approach monitors the time development of complex non-linear systems through the trajectory of a fixed-size distance matrix and its spectrum. We apply it to the S&P 500 cross section over three crisis decades, the 2001 dot-com bust, the 2007–2008 financial crisis, and the 2020 Covid crash, with three fixed-size observables on a fixed universe. The arccos distance matrix of the rolling return correlations reads the correlation geometry: its effective dimension collapses at the 2008 and 2020 crises, while the 2001 bust is a dispersed unwind. Read against machine-learning distance matrices, its spectrum stays in the un-relaxed, pre-learning regime with no low-dimensional manifold, so the market never learns its correlation structure or relaxes to a stationary geometry. Subtracting the market factor exposes a coherent sector rotation, whose name-level attribution identifies which stocks drive each crisis and in what order. At a short lookback these signals resolve precursors and forecast the endogenous 2008 crisis, though not the exogenous 2020 shock. The other two observables model the daily return and volatility rankings as Markov chains on their ranking spaces. The return chain has persistent, defensive-led bellwethers and near-reversible dynamics. The volatility chain is far more persistent, led by the financial sector, and is the only one to carry a weak, episodic arrow of time, flaring at market stress and matching volatility clustering and the Zumbach effect. All three matrices show coherent changes during market crashes.

1 Introduction

The eigenvalue spectrum of the equity correlation matrix is one of the oldest applications of random matrix theory outside physics. The bulk of the spectrum is well described by the Marchenko–Pastur law for a noisy sample covariance [1], while a small number of large eigenvalues sit above the bulk and carry the market and sector structure [2, 3]. A modern textbook account of random matrix theory for physicists, engineers, and data scientists, which beyond the general theory devotes an extended treatment to the tools that analyze financial correlation matrices, is given by Potters and Bouchaud [4]. During a crisis the cross section concentrates: correlations rise, the largest eigenvalue grows, and the effective number of independent factors drops [5, 6]. These facts are usually stated for a single correlation matrix, or for a slowly varying one, and read off from its eigenvalues.

Observable Matrix Dynamics (OMD) takes a different vantage [7]. Its central idea is to map the dynamics of a complex, high-dimensional system with stochastic and non-linear evolution onto a single fixed-size object whose own updates carry the time dimension. The object

*All calculations, numerical analysis, and manuscript preparation were performed by Claude Code with Opus 4.8 working as an AI assistant under author’s supervision. I would like to thank Miquel Noguer i Alonso, Ernest Bayer, Eric Berger, Galin Georgiev, Andrey Itkin, Charles Martin, Rudy Martin, and Alejandro Rodriguez Dominguez for very helpful discussions and comments on the manuscript. All remaining errors are my own. All Python code, analysis scripts, figures, and animation videos supporting this paper are available at https://github.com/ighalp/omd_finance.

compactifies the history into a fixed-size representation, produces a rich set of spectral and geometric diagnostics, and is universal across tasks, the same construction serving physical and learning systems alike. Mapping a variable-length input onto a fixed-size internal representation is a powerful and universal idea. For a vector-valued internal representation its power is supported by the success of recurrent neural networks, which fold an unbounded input history into the fixed-size state carried by their recurrent updates. OMD proposes a different fixed-size representation by an $N \times N$ matrix of pairwise distances: distances between particles in physical systems, or distances between the images (the internal representations) of N inputs to a neural network in machine-learning applications. For a market the particles are the stocks and the distances are the angular separations of their returns.

In this reading OMD treats the whole trajectory $\{M(t)\}_t$ of the fixed-size distance matrix as the object of study. Its spectral reading rests on Inference-BBS (I-BBS) [8], which infers a latent low-dimensional sub-manifold from a distance matrix by matching its spectrum to the Bogomolny–Bohigas–Schmit (BBS) theory of random distance matrices on Euclidean and spherical spaces [9, 10], itself part of the Euclidean random matrix program [11, 12]. OMD carries that inference along a trajectory and asks for quantities intrinsic to the trajectory rather than to any single snapshot, in the spirit of the frustrated-distance-matrix (FDM) relaxation dynamics [13]. The informative signals are spectral reorganizations that a scalar loss does not see, together with trajectory-level observables that link successive snapshots.

This paper applies the OMD reading to financial markets through three fixed-size matrix observables that give complementary views of the same daily history. The first is the arccos distance matrix $M_{ij}(t) = \arccos C_{ij}(t)$ (see Eq. (1) below) built from a rolling return correlation window, the geodesic that places the names on a hyper-sphere S^{d-1} . It reads the cross section through its correlations and is dominated by the market factor, the first principal component of the return correlation matrix. We read its spectrum for the effective dimension and the market-factor share, subtract the market factor to expose the sub-market sector geometry, and track its eigenbasis rotation with a projector drift and a matrix commutator.

The other two observables are rank-ordered transition matrices. Ranking the names each day by their running return, or by their running volatility, turns the relative ordering into a Markov chain whose transition matrix is a fixed-size observable, one for performance and one for risk.¹ Ranking is market-neutral by construction, since a common move leaves the order unchanged, so these chains isolate the relative dynamics that the market factor hides in $M(t)$. We read their spectra for persistence and mixing, their entropy production for time-reversibility, and their transfer entropy for the directed network of who moves whom. We track all three matrices across three crisis-containing decades and ask whether the trajectory view adds to the familiar eigenvalue story, and whether the observables agree.

The distance matrix adds three things beyond a single correlation snapshot. First, a short lookback sharpens the onset and exposes precursors that the standard two-year window averages away. Second, removing the market factor reveals that the sub-market sector geometry reorganizes on its own schedule, which for the Covid period runs well past the initial crash. Third, the trajectory-level diagnostics separate a rotation of the eigenbasis from a mere growth of an eigenvalue, and show that the market direction is nearly fixed while the sector direction rotates coherently, with a composition that identifies each crisis by industry.

A comparison with the machine-learning setting the observable comes from sharpens the interpretation. In the OMD experiments the distance-matrix spectrum acquires a low-dimensional manifold structure only as the network learns. The market spectrum keeps the smooth, structureless form of an un-relaxed, high-dimensional representation cloud throughout, with no sign that its correlation structure settles onto such a manifold. In this reading the market never

¹Treating the ordering as a Markov chain is a first approximation. The short memory and the absence of covariates can be relaxed by adding sector and firm-specific factors and higher-order memory as exogenous drivers of the transition matrix, an extension discussed in Section 7.

learns or relaxes to a stationary geometry, and is better described as a non-equilibrium object.

The ranking chain adds a market-neutral view of the same history. Its transition matrix has persistent leaders and laggards beyond what noise produces, and its migrations are coherent within sectors. Two further readings follow from the same discrete chain. Its entropy production, read from the forward and backward transition matrices, measures the time-irreversibility of the relative dynamics and finds the return ranking reversible throughout and a weak, episodic arrow of time in the volatility ranking. The volatility arrow is near zero in calm markets and flares at market-stress episodes, strongest at the 2002 dot-com bottom and the 2008 crisis. It is selective across the stress calendar we examine below, firing on sustained directional episodes but not on brief single-session shocks, so it tracks sustained reshuffling rather than volatility itself. Its transfer entropy gives a directed sector network of who moves whom, and finds the defensive sectors leading the market through a crisis. Ranking by volatility instead of return turns the same machine into a risk view, and the two transition matrices, one for performance and one for risk, are a matrix-form risk-return analysis in which the risk chain is far more persistent, the spectral signature of volatility clustering. The matrix views are consistent where they overlap and complementary where they do not. Both see the sector structure tighten toward 2020, and the utilities block that is the persistent residual cluster of the distance matrix is the same one that leads the information flow of the ranking chain in every crisis. A crash appears in the distance matrix as rising correlation and collapsing dimension and in the ranking as a burst of migration and irreversibility, the co-movement and the dispersion being two faces of the same move.

The third period, the Covid decade of 2015–2024, carries a run of well-documented market-stress events, and we use them to test how the spectral and matrix signals respond to shocks of different kinds. The events are the 2021 Archegos liquidation, the 2021 Omicron scare, the 2022 Russian invasion of Ukraine, the 2023 Silicon Valley Bank failure, the 2024 yen-carry unwind, and the 2024 hawkish-Fed repricing. The response is selective, and which signal moves identifies the kind of shock: the arrow of time fires on the directional deleveraging of Archegos, the spectral concentration on the correlation shift around the bank failure, while the brief symmetric shocks leave little trace in either.

The ranking chains are built from discrete states and read as Markov chains for a reason. Sorting the names into a fixed set of rank classes and treating the one-step class transitions as a Markov chain is a deliberate first approximation. Memory beyond one step and dependence on covariates are both real and can be added as extensions of this basic setting, yet the memoryless discrete chain already carries the effects we read here. Its advantage is estimation. The information-theoretic quantities we want, the entropy, the transfer entropy, and the entropy production, are hard to estimate for continuous, high-dimensional data. There they rely on nearest-neighbor or kernel density estimators whose bias and variance are delicate [14], and dedicated software exists to manage precisely this difficulty [15, 16]. On a discrete chain with a handful of classes the same quantities reduce to exact plug-in sums over an estimated transition matrix, cheap to compute and with a finite-sample bias that is easy to control against a reversible null. The numbers this produces are well defined and carry an intuitive reading, as the analysis below shows.

Related work. The noise-dressing of financial correlation matrices and the random matrix approach to cross correlations established the bulk-plus-outliers picture [2, 3], and hierarchical and network methods track how the correlation structure evolves in time [5]. The absorption ratio, the fraction of variance in the leading principal components, is a systemic-risk indicator close to the participation ratio used here [6]. The distance-matrix and trajectory-level tools we use are taken from the frustrated-distance-matrix study [13] and the OMD framework [7], which in turn build on [9, 11, 12]. The contribution here is empirical: to run those tools on real equity data across three crises and read what they add.

2 Data and the time-dependent distance matrix

The data are daily CRSP records for S&P 500 constituents over 1996–2024. For a chosen ten-year period we take the set of names that are index members for the entire period, including the two-year pre-roll needed to fill the first lookback, so that the cross section does not drift inside the period. We build the wide panel of daily total returns on that fixed universe and slide a lookback window of fixed length L in daily steps. At each measurement date t the correlation matrix $C(t)$ is the Pearson correlation over the last L observations. The Pearson correlation is the cosine-similarity Gram of the demeaned, unit-normalized return vectors, $C_{ij} = \cos \theta_{ij}$ with unit diagonal, so the distance matrix is the arccos of that Gram taken element-wise,

$$M_{ij}(t) = \arccos G_{ij}(t), \quad G_{ij}(t) = \frac{C_{ij}(t)}{\sqrt{C_{ii}(t) C_{jj}(t)}}, \quad (1)$$

the geodesic angle between the return directions on the sphere. For a raw correlation matrix $G = C$, so $M = \arccos C$; the renormalization to a unit-diagonal cosine Gram matters only when the input is not already a correlation, as for the deflated residual of Section 4.3. Here $M_{ij} \in [0, \pi]$ with a vanishing diagonal. Fixing the number of observations L keeps the aspect ratio $q = N/L$ constant in time, so the sampling noise in the spectrum is the same at every date and spectra are comparable across the period.

We study three periods, each centered on a crisis: 1996–2005 for the 2001 dot-com bust, 2003–2012 for the 2007–2008 financial crisis, and 2015–2024 for the 2020 Covid crash. The constant-membership universe holds $N = 244$, 265, and 309 names respectively at the two-year lookback. The default lookback is $L = 504$ trading days, about two years. When we shorten the lookback we cap the universe to the largest names by average market capitalization so that $N < L$ with margin, keeping $q \approx 0.75$ and the correlation estimate out of the singular $N > L$ regime: $N = 94$ at $L = 126$ (about six months) and $N = 192$ at $L = 256$ (about one year).

3 M-matrices in finance versus machine learning and physics

The distance matrix $M(t)$ that this paper tracks is borrowed from two recent settings, machine learning in the OMD and I-BBS papers [7, 8], and statistical physics in the frustrated-distance-matrix model [13]. In both the object was inspired by the Bogomolny–Bohigas–Schmit theory of random distance matrices [9, 10]. BBS itself is not concerned with dynamics. It describes the spectrum of the distance matrix of a single static snapshot of points distributed uniformly on the surface of a hyper-sphere. The OMD and FDM constructions carry that static object along a trajectory, and in both the underlying system relaxes to an equilibrium configuration, a trained representation or a settled particle arrangement. The BBS spectral characteristics, above all the delocalisation slope $\beta(t)$, then serve as a running diagnostic of that relaxation. A jump in $\beta(t)$ marks a structural change, and a stage with $\beta > 1$ signals the emergence of an effective low-dimensional manifold, as at the grokking transition of the OMD paper where the representation settles onto its learned sub-manifold.

The equity cross section, as the rest of this section shows, does not relax in this way, and β becomes a secondary diagnostic rather than a signature of learning. We first set out the spectral observables, then collect the caveats that keep the strict BBS structure from applying here, and finally read the finding against the machine-learning and physical cases.

We read two companion spectra at each date, following the I-BBS treatment of a random distance matrix. The correlation matrix $C(t)$ is the cosine-similarity Gram of the return directions on the sphere, and its ordered eigenvalues $\lambda_1 \geq \lambda_2 \geq \dots$ give the standard factor observables: the market-factor share $\lambda_1 / \sum_k \lambda_k$ and the participation ratio

$$\text{PR}(t) = \frac{(\sum_k \lambda_k)^2}{\sum_k \lambda_k^2}, \quad (2)$$

which counts the effective number of factors.

The distance matrix $M(t)$ adds a second reading, following the same I-BBS decomposition into a Perron mode and a power-law branch [9, 8]. The Perron eigenvalue $\Lambda_1(t)$, the single large positive eigenvalue of the angular-distance matrix, tracks the overall scale, the mean angular separation of the cross section. The largest-magnitude non-Perron eigenvalues on the window $K \in [2, \sqrt{N}]$ form a delocalised branch that decays as $|\lambda_K| \sim K^{-\beta}$, which for a uniform sample on the hyper-sphere S^{d-1} would give $\beta = d/(d-1)$ and an effective embedding dimension $d_\beta = \beta/(\beta-1)$. We fit β on that window directly from the eigenvalues of $M(t)$.

Figure 1 shows the spectrum itself, the eigenvalue magnitudes of $M(t)$ ranked on a log-log scale at three phases of each crisis, one year before onset, the crisis peak, and one year after, for the raw distance matrix (top) and the market-removed residual (bottom). The single Perron eigenvalue Λ_1 sits well above the rest at rank one, and the delocalised branch decays as the power law $|\lambda_K| \sim K^{-\beta}$ over the shaded window $K \in [2, \sqrt{N}]$. The crisis reads from the scale. For the 2008 and 2020 crashes the raw Perron contracts at the peak, from 392 to 317 and from 425 to 341, as the rising correlations shrink the angular separations, while the 2001 dispersion leaves it nearly unchanged. Removing the market factor stabilizes the scale, the residual Perron holding near 480 for 2008 and 519 for 2020 across all three phases, which locates the contraction in the market factor itself. The delocalised exponent is $\beta \approx 0.7$ throughout and steepens slightly at the peak in both readings.

Figure 1: BBS spectrum of the distance matrix $M(t)$, two-year lookback, raw (top) and market-removed (bottom), one column per period. Each panel shows the eigenvalue magnitudes $|\lambda_K|$ ranked on a log-log scale at three phases: one year before onset (blue), the crisis peak (red), and one year after (green). The Perron eigenvalue Λ_1 is the isolated point at rank one, and the delocalised branch $|\lambda_K| \sim K^{-\beta}$ decays over the shaded window $K \in [2, \sqrt{N}]$ where β is fit. The dotted vertical line marks $K = \sqrt{N}$, where the BBS shoulder between the delocalised and the localised branch would sit. The legend gives Λ_1 and β per curve.

Read literally, these spectra are a negative result for the strict BBS theory, and they differ in the same way from the I-BBS and OMD spectra obtained in machine-learning experiments and the FDM spectra obtained in physical systems. In all of those the delocalised branch resolves into flat angular-momentum quasi-multiplets, and a shoulder separates it from the localised bulk near $K \approx \sqrt{N}$. Our spectra show neither: the decay is smooth and monotonic, with no multiplet plateaus and no shoulder at the dotted $K = \sqrt{N}$ line, and removing the market factor does not recover the structure. Three effects plausibly wash it out. The lookback is finite with T of order N , so the correlation carries a Marchenko–Pastur noise bulk [1] that smears the fine

structure a noiseless manifold sample would show. The universe is small, $\sqrt{N} \approx 16$ to 18, so the delocalised window holds too few modes to resolve a shoulder. And the cross section is a few-factor-plus-noise structure rather than a uniform sample from a low-dimensional hyper-sphere, without the angular-momentum symmetry that produces multiplets. We therefore read only the coarse features, the Perron scale and the delocalised slope β , and treat the absence of the fine BBS structure as an open point, to be probed with longer lookbacks, larger universes, or noise-cleaned correlation estimators.

For the equity cross section the delocalised exponent stays below one throughout, near $\beta \approx 0.7$, and steepens toward one as a crisis concentrates the cross section. The naive inversion $d_\beta = \beta/(\beta - 1)$ then turns negative, which is not a physical embedding dimension. The delocalised reading is asymptotic in the sample size, valid in the BBS regime $N \gg d^2$, and at finite N the measured exponent falls below its large- N asymptote $d/(d - 1)$ by an I-BBS finite- N correction $\Delta\beta(N, d)$ that grows as N shrinks toward d^2 [8]. At our fixed N of a few hundred names, $\beta < 1$ is therefore consistent either with a finite latent dimension once that correction is restored, or with an embedding whose points depart from a uniform sample on the latent hyper-sphere. The market factor is a natural source of such non-uniformity, but re-measuring β on the market-removed distance matrix leaves it near 0.7, so the shortfall below one reflects the finite- N limitation at our fixed N rather than a market-factor artifact. We therefore report the participation ratio of $C(t)$ as the primary effective-factor count, with the Perron eigenvalue and the delocalised β of $M(t)$ as a secondary reading alongside it. We take β as an empirical power-law slope rather than as evidence that the underlying BBS geometry has formed.

Figure 2: A learning system can relax its distance-matrix geometry, and the market does not. (a) The grokking transformer of [7]: the train distance-matrix spectrum at initialisation, memorisation, and after grokking, the exponent rising from $\beta \approx 0.68$ through 0.39 to $\beta \approx 1.65$ as a shoulder near $K = \sqrt{N}$ (dotted) emerges. (b) Sparse parity undergoes the same phase transition more sharply, from $\beta = 0.65$ to 2.19. (c) At initialisation grokking, MNIST, and sparse parity share the un-relaxed regime, β between 0.65 and 0.81. Not all then relax through a transition, MNIST doing so only diffusively [7]. (d) The S&P 500 through the Covid crisis, one year before, at the peak, and after, its exponent near 0.7 to 0.8 with no shoulder, never relaxing.

Read through the OMD lens, this same negative finding becomes constructive, and Figure 2 makes it concrete. The un-relaxed, high-dimensional representation cloud of a learning system has a shared spectral signature at initialisation, before any training: a smooth power-law decay with β between 0.65 and 0.81, no quasi-multiplets, and no shoulder at $K = \sqrt{N}$. Grokking, MNIST, and sparse parity all begin with their untrained exponent β in this narrow range (panel c), so the value is a property of the un-relaxed cloud rather than of any one task, while experiments with intrinsically low-dimensional inputs start already structured. Learning can change it, but not for every system. Grokking and sparse parity pass through a geometric phase transition, the exponent rising to $\beta \approx 1.65$ and 2.19 with a shoulder at $K = \sqrt{N}$ (panels a and b), while MNIST relaxes only diffusively, without one [7]. The market carries the same un-relaxed signature and never departs from it, its exponent staying near 0.7 across the Covid crisis (panel d), with the crisis trajectories of this paper the direct evidence that the geometry

does not settle. The natural reading is that no learning of the correlation structure into a low-dimensional manifold takes place in the market. It never relaxes to an equilibrium M -matrix. Its correlation and distance matrices keep evolving with no stationary limit, which points to a non-equilibrium description, plausibly a non-equilibrium steady state (NESS) through periods of steady market conditions rather than a relaxed equilibrium.

These observations set the plan for the rest of the paper. Because the market never relaxes onto a low-dimensional manifold, β here plays a smaller role than in the OMD and FDM settings, where it is the main signature of learning and of relaxation to a steady state. We keep it as one diagnostic among several, its changes flagging shifts in the correlation structure alongside the Perron scale and the effective factor count, rather than as a primary readout. The dynamic characteristics that the moving M -matrix does carry are the subject of the sections that follow: the spectral collapse and the coherent eigenbasis rotation of the distance matrix, and the persistence, entropy production, and transfer entropy of the rank-ordered transition matrices that read the relative dynamics the market factor hides.

4 Results

Table 1 collects the spectral-collapse jumps at each onset, across three lookback windows, before the subsections develop them. The 2008 and 2020 crises share a signature, a collapse in the effective factor count and a jump in the market-factor share, while the 2001 dot-com period runs the other way. The size of the jump depends on the lookback. A short window resolves a sharper collapse, the Covid market share rising to 0.66 over a 126-day window against 0.48 over two years, while the 2001 dispersion signature, a rising factor count and a falling market share, emerges only at the longer windows and reverses at 126 days. The protagonist is the sector cluster that dominates the market-removed eigenvector’s rotation through the crisis, and the last column records whether the fragility signals forecast the crisis and the per-period forecast AUC at the 63-day horizon. The table covers the three crises. The Covid decade additionally offers a calendar of notable market-stress events, the 2021 Archegos liquidation, the 2021 Omicron scare, the 2022 Russian invasion of Ukraine, the 2023 Silicon Valley Bank failure, the 2024 yen-carry unwind, and the 2024 hawkish-Fed repricing, against which we test the sensitivity of the spectral and ranking-chain signals in the analysis that follows.

4.1 Spectral collapse onto the market factor

At the onset of the 2008 and 2020 crises the correlation spectrum collapses onto the market factor. For the Covid period, the mean pairwise correlation rises from 0.29 in the 2019 baseline to 0.47 in the March–April 2020 window, the market-factor share rises from 0.31 to 0.48, and the participation ratio falls from about nine effective factors to about four. The delocalised exponent of $M(t)$ steepens from $\beta \approx 0.73$ to $\beta \approx 0.79$ as the spectrum concentrates. The Perron eigenvalue of $M(t)$, the scale mode, contracts from about 394 to 335 as the rising correlations shrink the angular separations. Because the lookback is two years, the elevated state persists for about two years and then steps back down as the crash leaves the window.

Figure 3 aligns the three crises on a common time-to-onset axis. The 2008 and 2020 crises share the same signature: a sharp drop in the effective factor count and a jump in the market-factor share at $t = 0$. The 2001 dot-com period is the opposite. There the participation ratio peaks and the market-factor share dips near the onset. The bust was a dispersed, decorrelated unwind in which technology names pulled apart from the rest while the market as a whole held together. The observable therefore separates a correlated crash from a dispersion event, a distinction that a single rising average correlation would miss. Figure 4 shows the full trajectory for the Covid period, where each observable moves sharply at onset, plateaus for the lookback length, and reverts, with the 2022 bear market visible as a secondary feature.

Table 1: Summary across the three crises and three lookback windows. Effective factors is the participation ratio of $C(t)$, and market share is $\lambda_1/\sum \lambda$, each averaged over the calm year before onset and the first two months of the crash. The 126- and 256-day windows use a market-cap-capped universe so that $T > N$; the two-year (504-day) window uses the full constant-membership universe. The jumps sharpen at shorter lookback for the 2008 and 2020 collapses, while the 2001 dispersion signature, a rising factor count and a falling market share, emerges only at the longer windows. The last column gives the protagonist sector, the onset shape at the name level, and the per-period forecast AUC at the 63-day horizon.

Crisis	Lookback (days)	N	Eff. factors (calm $\rightarrow$ crash)	Market share (calm $\rightarrow$ crash)	Protagonist, onset forecast
2001 dot-com	126	94	16.5 $\rightarrow$ 14.9	0.20 $\rightarrow$ 0.20	Technology, staggered, no (0.46)
	256	192	19.8 $\rightarrow$ 23.6	0.20 $\rightarrow$ 0.15	
	504	244	22.9 $\rightarrow$ 25.3	0.19 $\rightarrow$ 0.17	
2007–08 GFC	126	94	5.1 $\rightarrow$ 3.8	0.43 $\rightarrow$ 0.51	Energy, gradual, yes (0.72)
	256	192	6.1 $\rightarrow$ 4.5	0.40 $\rightarrow$ 0.47	
	504	265	8.3 $\rightarrow$ 5.3	0.34 $\rightarrow$ 0.43	
2020 Covid	126	94	6.6 $\rightarrow$ 2.4	0.37 $\rightarrow$ 0.66	REITs, utilities, synchronized, no (0.49)
	256	192	7.3 $\rightarrow$ 3.3	0.36 $\rightarrow$ 0.57	
	504	309	9.0 $\rightarrow$ 4.4	0.32 $\rightarrow$ 0.48	

Figure 3: Three crises aligned on time-to-onset (years). Top: market-factor share $\lambda_1/\sum \lambda$ of $C(t)$. Bottom: effective number of factors, the participation ratio Eq. (2). The 2008 and 2020 crises collapse the factor count and raise the market share at onset; the 2001 dot-com period does the reverse, a dispersed decorrelated unwind. Two-year lookback.

Figure 4: Covid period, two-year lookback, $N = 309$. From top: mean correlation, market-factor share and effective factor count of $C(t)$, then the Perron eigenvalue and the delocalised β of the distance matrix $M(t)$. The dashed line marks the onset and the shaded band the two-year lookback window that follows it.

4.2 Lookback dependence and onset localization

The two-year window smears the crisis over its own length. A shorter lookback localizes the onset, at the cost of a noisier correlation estimate, and to keep the estimate out of the $N > L$ regime we cap the universe as described in Section 2. Figure 5 overlays the 126, 256, and 504-day lookbacks, all with $N < L$. At 126 days the Covid market-factor share spikes to about 0.73, against 0.52 at 504 days, and the effective factor count drops to about two, against about four. The short window also decays within about a year rather than sitting on the mechanical two-year plateau, tracking the actual recovery more faithfully. The short lookback resolves structure that the long window averages away. In the 2008 period the 126-day participation ratio shows a sharp dip in mid-2007, about a year before the Lehman failure, that is invisible at two years. This is the subprime and quant-liquidation tremor, and its early resolution is a concrete example of information that the trajectory view adds at short lookback.

4.3 Removing the market factor

To see the structure hidden under the dominant factor we remove the market factor by spectral deflation of the correlation matrix. At each window we diagonalize $C(t)$, take the leading eigenpair (λ_1, V_1) , the market factor, and subtract its rank-one projection,

$$C_{\text{res}}(t) = C(t) - \lambda_1 V_1 V_1^T, \quad (3)$$

Figure 5: Lookback comparison at 126, 256, and 504 days, all in the $L > N$ regime (the short windows use a market-cap-capped universe). Left: market-factor share. Right: effective factor count. Rows are the three crises, aligned on time-to-onset. The short window sharpens the onset and resolves the mid-2007 tremor that the two-year window smooths out.

which sends the market direction to a zero eigenvalue and leaves the residual correlation with leading eigenvalue λ_2 , the largest sector factor. The market-removed distance matrix is formed from the residual by the same construction as Eq. (1), renormalizing C_{res} to a unit-diagonal cosine Gram and taking the arccos element-wise, and its spectrum is read in the same I-BBS way. We report the Perron eigenvalue and delocalised β of M_{res} , and the leading-sector share and participation ratio of C_{res} .

Removal does what it should. The residual mean correlation sits at zero, the leading-sector share falls to between 0.06 and 0.12, and the effective factor count rises severalfold, from roughly seven to eighteen in the raw matrix to forty to eighty-five in the residual. The market factor dominates the raw geometry. The crisis signature nonetheless survives the removal. At each onset the residual leading-sector share still rises, the residual participation ratio still falls, and the residual β still steepens. Figure 6 shows the comparison. A crisis therefore reaches beyond a market-beta event: the sub-market sector co-movement also tightens, though far more mildly than the market factor. The timing can decouple. For the Covid period the residual leading-sector mode reaches its strongest concentration in 2021–2022, well after the March 2020 crash, tracking the post-crash sector rotation that the market factor does not see.

4.4 Eigenvector rotation through the crises

The eigenvalue observables above do not distinguish a rotation of the eigenbasis from a growth of an eigenvalue at fixed direction. To separate the two we use two trajectory-level diagnostics,

Figure 6: Raw versus market-factor-removed spectral dynamics, two-year lookback. Columns: mean correlation, leading-mode share and effective factor count of the correlation matrix, and the delocalised β of the distance matrix. Rows are the three crises. Spectral deflation zeroes the residual mean correlation and lifts the effective dimension, yet the onset signature persists in the residual, with a timing that can decouple from the market.

the top- K projector drift²

$$D_K(t_{\text{ref}}, t) = \|P_K(t) - P_K(t_{\text{ref}})\|_F, \quad P_K(t) = V_K(t)V_K(t)^T, \quad (4)$$

where $V_K(t)$ holds the top- K eigenvectors of $C(t)$, and the Frobenius norm of the matrix commutator

$$\mathcal{C}(t_{\text{ref}}, t) = \|[C(t_{\text{ref}}), C(t)]\|_F. \quad (5)$$

D_K measures whether the top- K eigenspace rotates between the two times, and $\mathcal{C}$ measures whether the two matrices share an eigenbasis, vanishing when they commute and growing with the amount of basis rotation. In the frustrated-distance-matrix study the informative eigenspace was the bottom- K block of the distance matrix [13]; here the market and sector structure sits in the top- K block of the correlation matrix, so we track the top- K rotation. We anchor at a pre-crisis reference, one year before onset, and follow the diagnostics as the window slides through the crisis. The onset itself is a fixed, hand-chosen date for each period, the dot-com decline in March 2001, the Lehman collapse in September 2008, and the Covid crash in March 2020. By construction D_K and $\mathcal{C}$ vanish at the anchor and rise as the eigenbasis rotates, so the drift minimum at the anchor (the green line) is a reference point where the measurement is zeroed, not a year-ahead precursor of the crisis. To judge whether a rotation is coherent or random, we compare the diagnostics against a random-subspace null, the level each would reach if the top- K eigenspace at time t were oriented at random relative to the anchor. For the projector drift, two independent random K -frames V_1, V_2 in $\mathbb{R}^N$ give $\|P_1 - P_2\|_F^2 = 2(K - \|V_1^T V_2\|_F^2)$, and $\mathbb{E} \|V_1^T V_2\|_F^2 = K^2/N$, so the expected drift is $\sqrt{2K(1 - K/N)}$, about 3.1 for $K = 5$ and N of a few hundred. For the leading-eigenvector overlap, two independent random unit vectors in $\mathbb{R}^N$ have root-mean-square overlap $1/\sqrt{N}$. These are the analytic analog of the eigenvalue-

²We thank Alejandro Rodriguez Dominguez for suggesting these two trajectory-level metrics.

randomized null of [13]. A drift near $\sqrt{2K(1-K/N)}$ or an overlap near $1/\sqrt{N}$ marks a fully scrambled eigenspace, and values far from those levels a coherent, partial rotation.

Figure 7 reports the diagnostics at the two-year lookback. The market direction amplifies while its orientation holds fixed. The raw leading eigenvector keeps an overlap near one, between 0.93 and 0.99, with its pre-crisis anchor through every crisis: the market factor grows in eigenvalue but keeps its direction, which is the nearly uniform positive combination of all names. The sector geometry is what reorganizes. With the market removed the leading sector eigenvector rotates strongly, its anchor overlap falling to about 0.5 for Covid and below 0.2 for 2008, and for the Covid period it keeps rotating through the 2020–2022 sector rotation rather than only at the March 2020 crash. The commutator gives a sharp onset marker complementary to the eigenvalue collapse: the norm $\mathcal{C}(t_{\text{ref}}, t)$ steps up abruptly at each onset, from zero at the anchor to about 43 for Covid and about 30 for 2008, as the correlation matrix ceases to commute with its pre-crisis self. At the 126-day lookback the step localizes to the onset and decays within about a year, against the mechanical two-year plateau of the long window (Figure 8). Throughout, the top- K projector drifts stay well below the random-subspace null. The rotation is coherent, the same conclusion that [13] reaches for its relaxation trajectory: the matrix trajectory carries information beyond the instantaneous eigenvalue sequence.

Figure 7: Eigenvector rotation through each crisis, two-year lookback. Blue is the raw correlation matrix, red the market-removed residual. Columns: top- K projector drift D_K from the anchor (see Eq. (4)), leading-eigenvector overlap with the anchor, the one-month local rotation rate, and the commutator norm $\mathcal{C}$ (see Eq. (5)). The vertical lines mark the anchor, one year before onset (green dotted), and the onset (crimson dashed). The horizontal grey dotted line in the first two columns is the random-subspace null defined in the text. The raw market eigenvector holds overlap near one, while the market-removed sector eigenvector rotates and the commutator steps up at onset.

4.5 Which sectors the rotating eigenvector loads onto

The rotating market-removed leading eigenvector is a sector portfolio, and its composition names the crisis. We classify each name into one of about ten sectors from its SIC code, a SIC-derived grouping in which pharmaceuticals and computing are pulled out of the broad

Figure 8: Eigenbasis reorganization measured by the commutator norm $\mathcal{C}(t_{\text{ref}}, t)$, 126 versus 504-day lookback, aligned on time-to-onset. The short window localizes the reorganization to the onset and decays within about a year; the long window shows the mechanical two-year plateau.

chemicals and manufacturing groups. At each date we take the energy fraction of the leading residual eigenvector in each sector, $\sum_{i \in s} v_{1,i}^2$, and normalize by the sector’s share of names to a concentration ratio, so that a value above one means the eigenvector over-weights that sector.

Figure 9 shows the result. Utilities is the most persistently concentrated cluster in every period: once the market is removed, the rate-driven utilities co-move as a standing block. On top of that baseline each crisis lights up its own sector. Technology concentration rises through 1999–2001 and collapses after the dot-com bust. Energy is the dominant residual cluster of the 2003–2012 period, already high in the 2005–2008 oil run, with financials rising as a second mode into and through the 2008 crisis. Energy flips from cold before 2020 to a leading sector in the Covid crash and the 2021 reflation. The market-removed leading eigenvector thus supplies both the timing of a regime shift, through the rotation and commutator of Section 4.4, and its identity, through the sector composition, where a single eigenvalue would give neither.

4.6 Name-level attribution: who moves, and who moves first

The sector statement resolves to individual names. We track the full per-name loading trajectory of the leading market-removed eigenvector at the two-year lookback, aligning the sign of $v_1(t)$ in time so the trajectory is continuous, take the pre-crisis anchor and the peak-rotation date where the eigenvector is farthest from the anchor, and rank names by their loading change. Ordering the top movers by when each crosses the halfway point of its shift, relative to onset, shows the sequence in which the rotation happens.

The movers are the specific protagonists of each crisis (Figure 10). In 2008 the largest loading moves are the energy names, the oil majors, offshore drillers, and oilfield-service firms such as Halliburton, Occidental, ConocoPhillips, Apache, and Schlumberger, which formed the dominant residual cluster of the oil supercycle and disperse through the crisis, while healthcare names move the other way. In 2020 the entire rate-sensitive block moves together: the real estate investment trusts, Simon Property, Ventas, Welltower, Host Hotels, Boston Properties,

Sectors the market-removed leading eigenvector rotates onto (504-day lookback)

Figure 9: Sector composition of the rotating market-removed leading eigenvector, two-year lookback. Left: heatmap of the concentration ratio, a sector’s fraction of the eigenvector divided by its share of names, in log₂ units, with onset dashed. Right: the same ratio at a pre-crisis, crash, and recovery date. Utilities is persistently the most concentrated cluster. On top of it, technology marks the 2001 period, the energy supercycle the 2003–2012 period with financials rising in 2008, and energy the 2020 period. The sectors are SIC-derived, so the real estate investment trusts that drive the 2020 name-level rotation (Figure 10) sit inside the Financials row here, whose concentration falls together with the utilities as energy rises.

and the utilities collapse from strongly positive loadings toward zero, with a software name moving the other way. At the sector level the eigenvector rotates out of this rate-sensitive complex and into energy, which takes over as the leading residual cluster through the crash and the 2021 reflation (Figure 9), so the yield-complex movers and the energy concentration are the two ends of one rotation. In 2001 the movers are defensive, healthcare and consumer staples gaining loading while utilities and telecom fall, the name-level counter-rotation to the technology cluster whose concentration peaks and collapses across the bust (Figure 9).

The ordering answers who moves first, and it matches the forecasting result of Section 4.7. For Covid the top movers all cross their half-shift within about two weeks of onset, a synchronized break with no early movers, which is the exogenous-shock signature. For 2001 there are genuine early movers, utilities and telecom shifting months ahead, consistent with the slow dispersed unwind. For 2008 the energy cluster reorganizes gradually across 2008–2010, so at the two-year lookback the half-shift dates fall around and after the trough, and a shorter lookback would place them earlier. The synchronized versus staggered contrast across the trajectories is the name-level face of why the 2008 crisis was forecastable from the correlation structure and

the 2020 crash was not.

Name-level attribution of the rotating market-removed eigenvector (504-day lookback)

Figure 10: Name-level attribution of the rotating market-removed eigenvector, two-year look-back. Left: top movers by loading change from the pre-crisis anchor to the peak-rotation date, blue for increasing and red for decreasing loading. Right: loading trajectories of those names, ordered by the timing of their half-shift crossing, with onset dashed. The 2020 movers change together at onset, the 2001 movers are staggered with early movers, and the 2008 energy cluster reorganizes gradually.

4.7 Early warning: which crises are forecastable

The observables above describe a crisis as it unfolds. A separate question is whether any of them warns of one in advance. We test this with a causal criterion: each 126-day signal at date t uses only the trailing window, and the label is a forward peak-to-trough drawdown of the equal-weight market beyond a threshold within the next 21 or 63 trading days. We score each signal by the area under the ROC curve, pooled over the three periods and broken out by period, using the rising mean correlation, the market-factor share, the negative participation ratio, the one-month rotation rate, and the commutator against the pre-crisis anchor.

The answer is regime-dependent, and that is the finding. The correlation-fragility signals, rising mean correlation, rising market-factor share, and falling participation ratio, give genuine early warning only for the 2008 crisis, which built up endogenously over a year: the per-period AUC is about 0.72 at the 63-day horizon, and the fragility crosses its eightieth-percentile level months before the trough. The same signals have no skill for the 2020 Covid crash (AUC about 0.49) or the 2001 dot-com unwind (AUC about 0.46). This is the correct behavior rather than a failure. An endogenous fragility measure can forecast a crisis that grows out of the correlation structure itself, and cannot forecast an exogenous shock such as a pandemic, or a dispersed decorrelated unwind. The pooled AUC, about 0.65 at 21 days and 0.56 at 63 days (Figure 11),

averages these regimes and understates the per-period contrast. The eigenvector rotation rate is coincident rather than leading, with an AUC near 0.49: it spikes as the eigenbasis reorganizes, which happens during the crash and not before.

Figure 11: Early-warning ROC for the 126-day signals against a forward market drawdown, pooled over the three crises. Left: drawdown over seven percent within 21 days. Right: drawdown over ten percent within 63 days. The fragility levels lead modestly in the pool and strongly for the 2008 crisis alone; the rotation rate is coincident. Signals use only trailing data, so the test is causal.

4.8 A geometric view: MDS embedding of the distance matrix

The spectral diagnostics summarize the distance matrix $M(t)$ through a handful of numbers. A direct geometric view places the names in space. Classical multidimensional scaling embeds $M(t)$ in three dimensions, one point per name, so that the Euclidean distances of the embedding reproduce the angular distances of $M(t)$ as closely as a three-dimensional picture allows. We keep the off-subspace residual of each name as a small radial puff, so the picture also carries the higher-rank content that three coordinates drop. Sliding the sharp 126-day window through each crisis turns the sequence of matrices into a moving cloud, aligned frame to frame by a rotation so it does not flip at random. The embedding is a visualization here, separate from the I-BBS spectral reading of $M(t)$.

Figure 12 shows four snapshots of the cloud for each crisis, read left to right as a calm baseline a year before onset, the onset, the crisis peak, and one year past the peak. The colour marks the crisis. Every name is grey in calm times. At the onset the colour kicks in, each name shaded by its total return over the following year and ranked across the universe, so green is the best performers and red the worst. Three months after the peak the colour reverts to grey, marking the return to normal conditions. Animated versions of these embeddings, over the full period and around each onset, accompany the paper.³

The geometry tracks the spectral story. In calm times the cloud is loose and roughly isotropic. At the 2008 and 2020 onsets it contracts as the correlations rise and the effective dimension collapses, most sharply for Covid, where the cloud shrinks to a dense knot at the April 2020 peak. The 2001 dot-com period barely contracts, the dispersed decorrelated unwind that the participation ratio already flagged, so its cloud stays spread. One year past each peak the cloud has re-expanded to its calm size and the colour has faded, the market back to normal. The picture is the spectral collapse seen directly: a rise in correlation is a contraction of the name cloud.

³The animated MDS embeddings, as single-period videos and a combined multi-panel animation of the three crises, are available in the paper's git repository, https://github.com/ighalp/omd_finance.

MDS embedding of the S&P 500 distance matrix $M(t)$ through three crises (126-day lookback)

Figure 12: MDS embedding of the distance matrix $M(t)$ through the three crises, 126-day lookback. Rows: the three periods. Columns: a calm baseline, the onset, the crisis peak, and one year after. Each name is a point, grey outside the crisis and, from the onset to three months past the peak, shaded by its return over the following year (green best, red worst).

5 Stock dynamics in the ranking spaces

The distance-matrix observable of the previous sections reads the cross section through its correlations. A complementary reading orders the names and follows the ranking. We use two orderings. The first ranks the names by their rolling mean return over a short window τ_{MC} ,

$$\bar{r}_i(t) = \frac{1}{\tau_{MC}} \sum_{s=t-\tau_{MC}+1}^t r_i(s), \quad (6)$$

a performance ordering. The second ranks them by their rolling volatility over the same window, a risk ordering. In either case rank 1 is the leader, the highest mean return or the highest volatility, and rank N the laggard, and the rank of a name is a discrete state whose evolution is a Markov chain on the corresponding ranking space.

Both orderings are market-neutral by construction. A common move, added to every return or scaling every volatility, leaves the order unchanged, so each ranking discards the market factor that dominates the raw correlation and keeps the relative, cross-sectional dynamics. The one-step dynamics of each ordering are carried by a time-dependent transition matrix,

$$P_{ab}^X(t) = \text{Prob}(\text{rank } b \text{ at } t + \Delta t \mid \text{rank } a \text{ at } t), \quad X \in \{R, V\}, \quad (7)$$

with R the return ordering and V the volatility ordering, each a fixed-size $N \times N$ observable estimated by pooling the rank transitions of all names over a window, with $\Delta t = 1$ day. Because each rank is occupied by exactly one name on every date, the marginal over ranks is uniform and the content lies entirely in the transition structure. The band of P^X around the diagonal measures how sticky a rank is, its off-diagonal mass how often names migrate, and the modulus of its second eigenvalue $|\lambda_2|$ sets the mixing time $-1/\log |\lambda_2|$ over which an initial ranking is

forgotten. The two chains are read side by side throughout this section, the return chain P^R for relative performance and the volatility chain P^V for relative risk.

We treat these rankings as Markov chains only as a first approximation, and do not claim that the dynamics on the ranking spaces are memoryless. The transitions carry higher-order memory, and the systematic and idiosyncratic factors specific to each firm modulate how a name moves between ranks. Both effects can be built in by driving the chain with exogenous covariates, such as firm characteristics or a lagged state, which would add realism to the dynamics on these spaces. In this paper we take the simplest view, reading each one-step transition matrix as a Markov chain and neglecting the covariates at leading order.

Four sources drive the migrations, and the ranking separates them. The market factor drops out. A sector move carries the sector’s members up or down together, so it appears as a coherent block migration and as a positive correlation between the one-step rank changes of same-sector names. A firm-specific move shifts one name against a still background. Pure noise reshuffles ranks at a rate set only by the overlap of successive τ_{MC} -day windows, which we read from an independent-return null that preserves N , the window, and the sample length. The excess persistence of the empirical chain over this null measures the systematic and idiosyncratic relative-performance structure, and the block coherence of the migrations measures the sector part.

The construction sits between two strands of the literature. Relative and peer-based measures are standard for security selection in a one-step, cross-sectional setting, where a name is compared against its peers and the shared factor exposure cancels by differencing. The relative-alpha measure of Jackwerth and Slavutskaya [17] nets a fund against its close peers, and the peer cohorts of Forsberg, Gallagher, and Warren [18] group funds by their return correlations and score each against its group, both market-neutral by construction in the same way our ranking is, and both used to select rather than to follow the whole cross section over time. The dynamics of the whole ordering, on the other hand, are the object of stochastic portfolio theory and its rank-based diffusions [19, 20], which center on the stationary capital-distribution curve and the collision dynamics of ranked weights. Our reading is the missing dynamic complement: the whole ordering as a fixed-size transition matrix $P(t)$, in place of the distance matrix $M(t)$, whose spectrum, entropy production, and transfer entropy we track through time rather than its stationary shape.

Figure 13 shows the two decile transition matrices for the Covid universe. The return chain is a broad band. The extreme deciles are the stickiest, the top and bottom holding their class from one day to the next with probability 0.71, while the middle deciles hold theirs between 0.26 and 0.42 and spread to their neighbours. The volatility chain is a much tighter diagonal, every decile holding with probability between 0.64 and 0.92, so a name keeps its risk rank far longer than its performance rank. Both chains exceed their independent-return nulls in every decile, the return chain most in the middle of the distribution and the volatility chain across the board, so each ordering carries a genuine persistence beyond the mechanical stickiness that the overlapping rolling windows produce on their own.

The spectra make the contrast quantitative (Figure 14). The return transition matrix has its second eigenvalue near 0.86 and the rest falling to zero within a few modes, so an initial performance ranking is forgotten in about seven days. The volatility eigenvalues stay high across the whole spectrum, the second near 0.97, and the mixing time is thirty to forty days, five to six times longer. This is the spectral signature of volatility clustering. Risk is persistent and predictable, a turbulent name stays turbulent for weeks, while relative performance churns fast, a leader today need not be one tomorrow. The two chains, built from the same names by the same construction, sit at opposite ends of the persistence scale.

The sector factor is visible directly in the migrations. In the return ranking the one-step rank changes of same-sector names correlate at 0.08 to 0.10 across the three periods, against near-zero for the full set, so sector members move up and down the performance ordering

together. This block coherence strengthens from the 2001 period to the Covid period, tracking the tightening sector structure of the correlation analysis. In the volatility ranking the same within-sector correlation is weaker, 0.03 to 0.05, because a name's risk rank is set more by its own idiosyncratic turbulence than by a sector-wide move.

The ranking dynamics carry a sharp crisis signature (Figure 15). At each onset the migration rate of both chains spikes, most violently for Covid, where the mean one-step change jumps by about half as the ordering reshuffles in the crash. The two chains then part in their mixing. The return mixing time drops slightly and sits at or below its pre-crisis level, so the turbulent aftermath churns the performance ordering a touch faster. The volatility mixing time instead rises sharply and stays elevated for a year or more, climbing toward sixty days after the 2008 crisis, so a crash makes the risk ordering more persistent even as it makes the performance ordering less so. This is complementary to the correlation reading. A crash raises the average correlation, which co-moves the names, and at the same time widens the dispersion of their magnitudes, which churns their performance order and locks in their relative risk.

Figure 13: Decile rank transition matrices for the Covid universe, at $\tau_{MC} = 10$ days for the return chain and 21 days for the volatility chain. (a) The return chain, a broad band with the extreme deciles holding at 0.71 and the middle deciles spreading to neighbours. (b) The volatility chain, a tight diagonal holding between 0.64 and 0.92. (c) The per-decile stay probability of the two chains against their independent-return noise nulls (open circles), exceeded in every decile.

Figure 14: Spectra and mixing of the two ranking chains. (a) Moduli of the decile transition-matrix eigenvalues ranked by magnitude, with the return chain (blue) and the volatility chain (red) each drawn for all three periods as three near-coincident curves. The volatility spectrum stays high in every period, so the volatility chain mixes slowly, while the return spectrum decays quickly. (b) The corresponding mixing times, one bar pair per period, about seven days for the return ranking and thirty to forty for the volatility ranking.

Figure 15: Ranking-space dynamics through the crises, return and volatility. In both columns the return chain (blue) is on the left axis and the volatility chain (red) on the right, each on its own scale, since the two chains move over very different ranges. Left: the migration rate, the mean one-step class change per name over N , as a 21-day mean, spiking at each onset for both chains. Right: the mixing time of the decile chain on a 252-day window. The return mixing time stays near a week and dips as an onset passes, while the volatility mixing time is an order of magnitude longer and rises and stays elevated after each onset. The dashed black line marks the crisis onset used throughout the paper, 1 March 2001 for the dot-com period, the Lehman collapse on 15 September 2008 for the financial crisis, and 1 March 2020 for the Covid period.

5.1 Entropy production of the ranking dynamics

The rank transition matrix invites a further reading from stochastic thermodynamics. A stochastic process is time-reversible only if its forward and backward paths are equally likely, and the failure of that balance is measured by the entropy production, the Kullback-Leibler divergence between the forward and backward path probabilities [21, 22]. A recent application of this stochastic-thermodynamic reading to financial markets, computing entropy production and the second law for cryptocurrencies, is given by Georgiev [23]. For a one-step transition with forward matrix P , time-reversed matrix $\tilde{P}$, and initial and final marginals p and p' , the total entropy production is

$$\sigma = \sum_{ab} p_a P_{ab} \log \frac{p_a P_{ab}}{p'_b \tilde{P}_{ba}} = \underbrace{\sum_{ab} p_a P_{ab} \log \frac{P_{ab}}{\tilde{P}_{ba}}}_{\sigma_{\text{med}}} + \underbrace{H[p'] - H[p]}_{\sigma_{\text{sys}}}, \quad (8)$$

the sum of a medium (irreversibility) part and a system entropy change [21, 24]. In an information-engine setting the backward matrix $\tilde{P}$ is often hidden, and only a lower bound on σ is available [24]. Here the whole trajectory is observed, so both the forward and the backward transition matrices are estimated directly from the rank data.

For the ranking chain the class marginal is fixed by the permutation structure, a fixed number

of names in each class at every date, so it is identical before and after a step and the system term vanishes exactly. Estimating the backward transitions from the reversed-time rank data transposes the joint, so the entropy production over an interval Δt is the divergence between the forward joint rank-transition distribution $\mu_{ab}(\Delta t) = \text{Prob}(\text{rank } a \text{ at } t, \text{rank } b \text{ at } t + \Delta t)$ and its time reverse $\mu_{ba}(\Delta t)$,

$$\sigma(\Delta t) = \sum_{ab} \mu_{ab}(\Delta t) \log \frac{\mu_{ab}(\Delta t)}{\mu_{ba}(\Delta t)}, \quad (9)$$

which is non-negative and vanishes exactly when μ is symmetric, that is when the rank dynamics satisfy detailed balance. It measures the time-irreversibility of the relative-performance dynamics. Any nonzero σ is a genuine breaking of time-reversal symmetry, so the relevant question is not whether it vanishes but how large it is. A small σ marks dynamics that are only weakly non-equilibrium, close to the reversible, equilibrium limit rather than far from it. A symmetric diffusion of ranks produces none. A directed flow, such as the asymmetry between a fast crash and a slow recovery or a momentum-then-reversion cycle, produces a positive current $J_{ab} = \mu_{ab} - \mu_{ba}$ and a positive σ .

Figure 16 reports the estimate for both chains. Both are close to detailed balance: the decile entropy production is of order 10^{-3} nats per step, small because rank motion is nearly one-dimensional, and a birth-and-death chain on a line is reversible in steady state. What structure there is has a clear timescale. Panel (a) shows that $\sigma(\Delta t)$ is small at one day, rises to a maximum near the rolling-window length, ten days for the return chain and about twenty for the volatility chain, and decays for longer intervals. Shorter intervals share most of their averaging window and move the ranks reversibly, while longer intervals let the chain mix back toward the uniform distribution. Panel (b) shows the probability current J_{ab} of the volatility chain for the Covid universe, an antisymmetric pattern concentrated near the diagonal and at the extreme classes, the signature of the systematic circulation that carries its arrow of time. Panel (c) tracks the rolling entropy production of both chains through the crises. Both lift in raw terms after each onset, and the volatility chain lifts far more, most sharply at the Covid onset, as the fast drops and slow recoveries of the crash raise the raw asymmetry above its calm-time level. Whether that raw lift is a genuine arrow or a finite-sample response is what the surrogate test settles below.

Figure 16: Entropy production of the ranking-space Markov chains, return and volatility. (a) $\sigma(\Delta t)$ from Eq. (9) against the time interval, return (solid) and volatility (dashed), each peaking near its own rolling-window length. (b) The probability current $J_{ab} = \mu_{ab} - \mu_{ba}$ of the volatility chain for the Covid universe, the antisymmetric circulating flow. (c) Rolling entropy production on a 63-day window against time-to-onset, return (solid) and volatility (dashed); the volatility chain lifts far more, spiking at the Covid onset.

The non-negativity of the entropy production is automatic. Equation (9) is a Kullback-Leibler divergence, so $\sigma \geq 0$ by construction, the one-step form of the second law, and it is

exactly what makes the forward and backward paths statistically distinguishable, the operational content of the arrow of time [25]. A positive value therefore does not by itself establish an arrow. The plug-in estimator is biased upward at finite sample, and the question is whether the observed σ exceeds what a reversible process of the same size would give. We test this by comparing each block of the chain against a detailed-balance surrogate, a reversible chain matched to the block’s marginals and sample size, and reading the excess of the observed entropy production over the surrogate. Figure 17(a) reports this excess as a z -score across 1996–2024 for one fixed whole-span universe.

The answer is that the return-ranking dynamics are close to detailed balance. Its z -score stays near zero across the span and never drifts upward, so no irreversibility accumulates. A direct test is decisive. Comparing the entropy production of the one-year window after each onset against the reversible surrogate, no crisis is significantly above the null, and the 2008 and 2020 windows sit slightly below it, so the year that follows a crash restores reversibility in the return ranking. Pooling the whole 1996–2024 span into a single estimate, over a million transitions with negligible bias, is equally decisive for a general arrow: the entropy production stays within statistical error of the reversible null at every resolution, and slightly below it at the decile level. In relative-performance space the market is therefore close to time-reversible, near equilibrium. This is consistent with what is known of time-reversal asymmetry in finance, which is pronounced in the volatility, through the Zumbach effect where past volatility forecasts future volatility more than the reverse [26], and weak at the level of the return ordering that the ranking reads. The raw entropy production still lifts after a crisis, as Figure 16(c) shows, but the lift is largely the finite-sample and structural response rather than a large excess over reversibility. It also lags the spectral jump by several months, because the irreversible signature needs both the fast crash and the slow recovery in the window before the forward and backward transitions differ.

Comparing the two chains isolates the arrow of time, and resolving it in time shows where it concentrates. Time-reversal asymmetry in markets is known to reside in the volatility rather than the returns, so the volatility chain should carry an arrow that the return chain does not. Figure 17 tracks the entropy-production z -score of both chains quarterly across 1996–2024 on one fixed universe, with the market-stress episodes shaded. The return chain stays near the reversible null throughout, rarely clearing the five-percent line and with no systematic tie to a crisis. The volatility chain is reversible in calm times, its baseline sitting slightly below zero, but carries a weak, episodic arrow that flares at market stress.

The largest flares are the 2002 dot-com bottom, reaching $z \approx 8$, and the 2007–08 financial crisis at $z \approx 4$, with further flares at the 2018 selloff and through the 2020–21 volatility regime. Testing the trace against a calendar of documented single-session stress events, marked on the figure, sharpens what it measures. Of those events only the March 2021 Archegos liquidation leaves a clear arrow, at $z \approx 5$, with the August 2024 yen-carry unwind a marginal one. The Omicron scare, the SVB failure, and the hawkish-Fed repricing raise volatility sharply yet leave no arrow at all. The reason is twofold. A one-session shock is diluted inside a quarterly block, and a spike that falls and recovers symmetrically carries no time asymmetry to begin with. The arrow responds to sustained, directional reshuffling of the cross section, the forced multi-day deleveraging of Archegos or the grinding drawdowns of the large crises, rather than to volatility on its own.

The absolute entropy production stays small at every date, so even the flares are only weakly non-equilibrium, yet they are genuine and they sit where the stochastic-volatility literature places the market’s arrow of time. The March 2020 Covid crash is the informative exception. Too brief for a quarterly block to resolve, its arrow does not appear in the crash quarter itself but in the sustained high-volatility regime that runs into 2021. A pooled estimate over a whole multi-year period inherits this smearing, which is why the arrow is better read from the time-resolved trace than from a single number per crisis.

The same figure carries two of the distance-matrix spectral diagnostics on the same axis, as a check on whether they move where the arrow does not. Panels (b) and (c) track the market-factor share λ_1/N of $C(t)$ and the delocalised exponent β of $M(t)$, computed on the hundred largest-cap names and shown at both a half-year (126-day) and a one-year (252-day) rolling window. Both rise at every crisis regime, the share climbing from a calm level near 0.33 to 0.58 in 2008 and 0.68 at Covid and the exponent steepening from near 0.49 toward 0.80, so a crash concentrates the cross section and lifts the whole battery of diagnostics at once. They also separate the single-session events by type. The share and the exponent both lift around the SVB banking failure, where the arrow of time is flat, so the spectral concentration reads a correlation-regime shift that the arrow does not, whereas Archegos moves the arrow while leaving the share at its calm level, a directional reshuffling without broad concentration. The two windows agree on this structure, the longer one smoothing the shorter, and at either window these are regime indicators that flag the sustained stress around an event rather than the single session.

The entropy production so far is a per-step portfolio average, but stochastic thermodynamics also assigns an entropy production to each single trajectory, here the path of one firm through the volatility ranking over the whole interval. The thermodynamic force $F_{ab} = \log(\mu_{ab}/\mu_{ba})$ is a property of the pooled chain, and firm i 's entropy production $\Sigma_i = \sum_t F$ is the force accumulated along its own trajectory, the total over the decade rather than a rate. Dividing Σ_i by the 2495 daily steps returns a per-step rate, and the portfolio average of that rate is the pooled σ exactly. Figure 18 decomposes the Covid-decade volatility arrow this way, and the distribution is very uneven. A handful of firms accumulate about 3 nats over the decade, five to six times the portfolio-average 0.5, so the market's small arrow of time is not spread evenly but concentrated in a few names whose volatility rank rides the systematic fast-up, slow-down circulation of volatility clustering. The leaders in this interval are Textron, Symantec, News Corp, Conagra, and Mohawk, a mix of industrial, technology, and consumer names rather than a single sector.

5.2 Transfer entropy across sectors: who moves whom

The entropy production is a single number for the whole chain. A finer, directional question is whose rank movements predict whose. It is answered by the transfer entropy [27], the reduction in uncertainty about one series' next state gained from a second series' present, beyond the first series' own present,

$$\text{TE}(S \rightarrow T) = \sum p(t', t, s) \log \frac{p(t' | t, s)}{p(t' | t)}, \quad (10)$$

where t' is the next state of the target T , and t and s the present states of T and the source S . It vanishes when S carries no information about the future of T that T does not already carry. On continuous return series the transfer entropy needs a nearest-neighbor estimator and a surrogate test [28]. The ranking removes that difficulty. With the states already the rank classes, Eq. (10) is an exact plug-in histogram estimator, and only a shuffle of the source is needed to subtract the finite-sample bias floor.

We coarse-grain each sector to the tercile of its mean rank, hot, warm, or cold, and compute the surrogate-corrected transfer entropy between every ordered pair of sectors, in both rankings. The net flow of a sector, its total outgoing minus incoming transfer entropy, ranks it as a net sender, a leader whose moves predict others, or a net receiver, a follower. Figure 19 shows the two directed networks for the Covid period (panels a and b) and the crisis-window leadership of both (panel c). In the return ranking the crisis leadership is a flight to quality. Utilities is the dominant net sender in the 2008 and Covid windows, with health care close behind, and is among the leaders in 2001, so the rate-driven defensive sectors set the pace of the performance ordering while the cyclical follow. This is the same utilities block that stands out as the

Diagnostics over 1996--2024

Figure 17: Diagnostics over 1996–2024, resolved in time, against the market-crisis regimes (shaded) and public market-stress events (numbered dotted lines: 1 Archegos, 2 Omicron, 3 Russia/Ukraine, 4 SVB, 5 yen-carry unwind, 6 hawkish Fed). (a) The arrow of time, the entropy-production z -score of the decile chain against the reversible detailed-balance null on 63-day blocks for one fixed whole-span universe, for the return ranking (blue) and the volatility ranking (red), with the shaded excess above the five-percent line marking the periods of significant irreversibility. The return arrow rarely clears the five-percent line, while the volatility arrow flares at market stress, strongest at the 2002 dot-com bottom ($z \approx 8$) and the 2007–08 crisis ($z \approx 4$). Among the marked single-session events only Archegos leaves a clear arrow. (b) The market-factor share λ_1/N and (c) the delocalised exponent β of $M(t)$, computed on the hundred largest-cap names and shown at a 126-day (solid) and a 252-day (dashed) rolling window. Both rise at every crisis regime and around the SVB banking stress where the arrow is flat, while Archegos moves the arrow but not the share. The two windows agree, the longer one smoothing the shorter, and both read regimes rather than single sessions.

Entropy production along single-firm trajectories: a few firms carry the market's arrow of time

Figure 18: Entropy production along single-firm trajectories, volatility chain, Covid decade. (a) The twelve firms with the largest single-trajectory entropy production $\Sigma_i = \sum_t F$, the thermodynamic force accumulated along each firm's own path through the volatility ranking over the decade, coloured by sector. The portfolio average of Σ_i (dashed, 0.5 nats) is the pooled entropy production integrated over the interval, and the top firms exceed it five to six times. Dividing Σ_i by the 2495 daily steps gives the per-step rate. (b) The volatility-decile trajectories of the top three firms (63-day mean), the single paths whose entropy production panel (a) reports, with the Covid onset dotted.

persistent residual cluster in the distance-matrix analysis, identified here as the crisis-time source rather than only the most coherent group.

The volatility ranking tells a different story about the same crises. There the net senders are the financials, dominant in both the 2008 and the Covid windows, while utilities turns from the strongest performance leader into a risk follower, one of the largest net receivers. The two networks split the crisis into a performance channel, where defensives lead a flight to quality, and a risk channel, where the financial sector's turbulence propagates first. In the 2001 dot-com period, which was not a banking crisis, financials lead neither channel and the volatility leadership is diffuse. Reading who moves whom in performance and who moves whom in risk gives two directed networks that a single return series would merge into one.

Figure 19: Directed transfer entropy between sectors, each represented by the tercile of its mean rank, surrogate-corrected, for the Covid period. (a) The net sector transfer-entropy matrix $S \rightarrow T$ for the return ranking. (b) The same for the volatility ranking. (c) The crisis-window net flow, return against volatility: utilities leads the return channel while financials lead the volatility channel.

5.3 The lead-lag network at the name level

The sector transfer-entropy network resolves to individual names, in both rankings. Computing the discrete transfer entropy between every pair of stocks in tercile rank space and ranking each by its net flow, its outgoing minus incoming transfer entropy, gives a directed lead-lag network whose senders are bellwethers and whose receivers are followers (Figure 20). In the return ranking for the Covid decade the bellwethers are the utilities, FirstEnergy, Exelon, Pinnacle West, Ameren, and their peers, whose rank moves predict the rest, and the followers are the financials, Prudential, Truist, MetLife, and Morgan Stanley. In the volatility ranking the roles rotate. The risk leaders are the financials and real-estate names, Loews, Truist, Boston Properties, and Kimco, whose turbulence moves first, and the risk followers are the industrials and defensive names, General Dynamics, Roper, and Aon. Truist is a clean instance of the reversal, a follower in performance and a leader in risk. Aggregating the stock net flows by sector (panel c) reproduces the sector split, utilities leading the return channel and following the risk channel while financials do the reverse. The name-level network names the specific bellwethers behind each channel, the rate-driven utilities that set the pace of relative performance and the financials whose risk propagates first.

Figure 20: Stock-level lead-lag network in ranking space, Covid decade. (a) Return ranking: the net transfer-entropy flow per name, the top twelve bellwethers and bottom twelve followers, blue for senders and red for receivers, with utilities leading and financials following. (b) Volatility ranking: the risk leaders and followers, where financials and real estate lead. (c) The stock net flows aggregated by sector, return against volatility, showing the role reversal between the two channels.

5.4 Co-movement and dispersion

The two matrix views correspond to a decomposition of the daily cross section. Each day the panel of returns is the sum of a market move, shared by every name, and a residual spread around it, the cross-sectional dispersion. The distance matrix is dominated by the market factor and reads the systematic co-movement; the ranking chain is market-neutral and reads the residual dispersion. A crash amplifies both at once (Figure 21a): the mean correlation rises as the names move together, and the cross-sectional dispersion spikes as their magnitudes spread apart.

In the distance matrix the co-movement and the effective dimension are two readings of one number. The participation ratio is a tight, almost deterministic decreasing function of the mean correlation, the same curve across all three periods, the two almost perfectly anti-correlated near -0.95 (Figure 21b): as the cross section co-moves, its effective dimension collapses. In the ranking chain the dispersion and the rank migration rise together through the crash (Figure 21c),

the widening spread of relative performance churning the order. The distance matrix and the ranking are the two halves of the same daily cross section, the systematic and the idiosyncratic, each amplified by a crisis.

Figure 21: Co-movement and dispersion, the two components of a crash. (a) Aligned on onset, the mean correlation (co-movement, distance matrix) and the cross-sectional dispersion (ranking chain) both rise at the crash. (b) The participation ratio against the mean correlation, a tight inverse curve shared by the three periods. (c) The dispersion and the rank migration rate rise together through the crash.

6 Discussion

The eigenvalue collapse at a crisis is a known fact, on its own a scalar statement that correlations rise and the effective dimension falls. The trajectory view refines it in three ways a single correlation matrix cannot. The lookback comparison shows that the standard two-year window is a low-pass filter that delays the onset and hides precursors such as the mid-2007 tremor, while a short window recovers them at the price of sampling noise that a market-cap cap keeps under control. The market-factor removal shows the crisis is not only a market-beta event, and that the sector geometry has its own clock, most clearly in the 2015–2024 Covid period, where the sector rotation runs a year or more past the crash. The rotation diagnostics separate what the eigenvalue observables conflate, a growth of the market eigenvalue at fixed direction from a genuine rotation of the sector eigenbasis, with the random-subspace null certifying the rotation as coherent.

The persistence of utilities as the most concentrated residual cluster is worth a comment. After the market is removed, the strongest remaining common factor is not one of the cyclical sectors but the rate-sensitive utilities, which move together on the level and slope of interest rates rather than on the business cycle. The crisis-specific clusters, technology in 2001, the energy supercycle in 2003–2012, and energy again in 2020, appear as concentrations on top of this standing utilities block.

The forecasting test and the name-level attribution tell one story from two sides. The fragility signals forecast only the endogenously-building 2008 crisis, and the movers show why: in 2008 the energy cluster reorganizes gradually, giving the signal time to rise, whereas in 2020 the rate-sensitive block breaks in a single synchronized step at onset, with nothing to read in advance. The synchronization of the 2020 movers is the name-level reason the ROC finds no lead.

The distance matrix and the two ranking chains give a coherent account from opposite directions. The distance matrix is dominated by the market factor and reads a crisis as the collapse of the correlation geometry onto that mode, while the ranking chains remove the market by construction and read the same crisis as a churn of the relative order, one chain for performance and one for risk. They agree on the sector structure, the one signal each can

see: the sector eigenvector of the market-removed distance matrix and the within-sector co-migration of the return chain both strengthen from 2001 to 2020. On the crash itself they are complementary. A rise in average correlation and a burst of rank migration are the co-movement and the dispersion of the same violent move, the first visible only with the market kept in the matrix, the second only after the ranking removes it.

The two ranking chains are a matrix-form risk-return analysis in their own right, sitting at opposite ends of the persistence scale, the return chain forgetting an ordering in about seven days and the volatility chain holding one for thirty to forty. Their entropy production splits the same way, and both stay small, so the market is at most weakly non-equilibrium in its relative order. The return chain stays near the reversible bound, close to time-reversible, while the volatility chain carries a weak, episodic arrow that flares at market stress, reaching $z \approx 8$ at the 2002 dot-com bottom and $z \approx 4$ at the 2008 crisis, placing the market's arrow of time in the volatility as the Zumbach effect predicts. Their transfer-entropy leadership splits too, the rate-driven utilities and other defensives leading the return channel through the 2008 and Covid crises in a ranking-space flight to quality, while the financial sector leads the volatility channel, its risk propagating first. Those same utilities anchor the market-removed residual as its most coherent cluster, so coherence and the performance lead name one sector while the risk lead names another.

These signals are coupled, but they are ordered in time rather than simultaneous. Figure 22 aligns five of them on the crisis onset for each period: the effective factor count (measured by the participation ratio, PR), the commutator norm, and the delocalised exponent β from the distance matrix, and the entropy production and the defensive transfer-entropy leadership from the ranking chain. For the 2008 and 2020 crises the three distance-matrix signals fire at the onset itself, the factor count collapsing, the commutator stepping up, and β steepening as the crash enters the window. The two ranking-chain signals respond more slowly, over the following months, as the raw entropy production lifts and the defensive sectors take over the transfer-entropy leadership. The lag has a clear origin: the spectral observables read the instantaneous correlation state, while the ranking-chain quantities read a time-directional property that needs both the fast crash and the slow recovery before it registers. The five are still co-dependent readings of one reorganization of the cross section, a loss of dimension, an eigenbasis rotation, a steepening slope, a rise in irreversibility, and a shift of directed influence toward the defensives. The 2001 bust, the dispersed regime, is the exception in the distance-matrix rows, where the factor count rises rather than falls, while the ranking rows still register the event. The coupling across the two matrices, one built from correlations and one from ranks, one keeping the market and one removing it, is the strongest statement that they are watching the same dynamics.

The diagnostics differ in what they are sensitive to, and a calendar of documented market-stress events brings the difference out. A sustained crash lights up the whole battery, dimension collapse and eigenbasis rotation in the distance matrix, an entropy-production lift and a leadership shift in the ranking chains. Brief single-session shocks are another matter, and the arrow of time is the clearest case. It fires on sustained, directionally asymmetric reshuffling, the 2002 and 2008 drawdowns and the multi-day forced deleveraging of the 2021 Archegos liquidation, and stays flat through one-day macro shocks such as the Omicron scare, the SVB failure, or a hawkish-Fed repricing, even when those move the VIX sharply. The selectivity is a feature rather than a limitation. The entropy production measures directional irreversibility, so it separates the events that leave a persistent, time-asymmetric imprint on the cross section from those that spike volatility and mean-revert within the window.

The spectral reading places the market next to the learning systems the distance-matrix observable is borrowed from, and the contrast is the sharpest statement of what the market does not do. In some machine-learning experiments, grokking and sparse parity, the distance matrix undergoes a geometric phase transition as the network learns: its delocalised exponent rises through one, quasi-multiplets appear, and a shoulder forms at $K \approx \sqrt{N}$ as the representation

Co-dependence across a crisis, aligned on onset; Covid column marks public stress events

Figure 22: Co-dependence of the matrix views across a crisis, aligned on onset (crimson dashed at year zero), one column per period and out to five years past onset. Rows, top to bottom: the effective factor count (the participation ratio, PR) of the distance matrix, the commutator norm, the entropy production of the ranking chain, the defensive-sector transfer-entropy leadership, and the delocalised exponent β of the distance matrix. The first row superimposes the market-factor share λ_1/N (grey dashed, right axis) on the PR, the same concentration read as a rising share and a falling factor count. The entropy-production row draws the return chain in the period colour and the volatility chain in red, its excess over the dotted reversible null the time-irreversibility. At the 2008 and 2020 onsets the distance-matrix signals fire at the crash and the ranking-chain signals follow over the next months. In the Covid column the numbered dashed lines mark public stress events (1 Archegos, 2 Omicron, 3 Russia/Ukraine, 4 SVB, 5 yen-carry unwind, 6 hawkish Fed).

settles onto a low-dimensional sub-manifold. The market’s distance matrix does none of this. Its exponent stays near 0.7 across all three crises with no quasi-multiplets or shoulder, and the crisis trajectories of this paper are direct evidence that the geometry never settles. The market carries the signature of an un-relaxed, high-dimensional representation cloud, the state a learning system occupies before training: it does not learn its correlation structure into a low-dimensional geometry, and its distance matrix is a non-equilibrium steady state through calm periods that a crisis drives further from equilibrium rather than toward a new one. This turns the absence of BBS structure from a negative finding into a positive one, and sets the terms for the trajectory diagnostics that follow: the market is watched not for signs of relaxation, which never come, but for how far each crisis pushes an object with no equilibrium to return to.

Several limitations are worth stating. The role of the delocalised exponent β and the caveats on the strict BBS reading were set out in Section 3 and are not repeated here. The sector map is SIC-derived rather than GICS, so a handful of names sit in a coarser bin than a practitioner classification would assign, though the crisis-time leadership finding rests on utilities, a clean SIC bin, and is not sensitive to the ambiguous cases. The early-warning areas under the ROC are in-sample and per-period, a descriptive comparison rather than an out-of-sample forecast, so their regime-dependence is qualitative. The market-cap cap used for the short lookbacks changes the universe between lookbacks, so the 126 and 504-day curves are not on identical name sets, though the crisis-relative changes are insensitive to the cap. Finally, the anchor for the rotation diagnostics is a fixed pre-crisis date, so the reported drifts and commutators are relative to a calm reference and are not meant as an absolute scale.

7 Summary and outlook

We read the S&P 500 cross section through three fixed-size matrix trajectories. The arccos distance matrix reproduces the known spectral collapse at crises and adds three things beyond it: a sharper, precursor-resolving onset at short lookback, a sub-market sector reorganization with its own timing under market removal, and a coherent rotation of the sector eigenbasis whose composition names each crisis by industry. The same trajectory-level diagnostics that separate a coherent rotation from random tumbling in a physical relaxation problem [13] carry over unchanged. The other two matrices order the names each day by return and by volatility, two market-neutral Markov chains that read the relative dynamics the market factor hides. They are a matrix-form risk-return analysis. The return chain mixes in about a week and the volatility chain in a month or more, and their transfer-entropy leadership, resolved down to individual bellwethers, splits between the defensive utilities that lead the performance channel through the 2008 and Covid crises and the financial sector that leads the risk channel. Their entropy production splits the same way, both small in absolute terms. The return chain stays near the reversible bound at all times, so relative performance is close to time-reversible, while a weak, episodic arrow of time surfaces in the volatility chain, the ranking-space form of volatility clustering and the Zumbach effect. Resolved quarterly across thirty years, the volatility arrow is near zero in calm markets and flares at market-stress episodes, strongest at the 2002 dot-com bottom and the 2008 crisis. This episodic, stress-driven irreversibility, small but genuine, is a reading the discrete Markov chains make accessible where a continuous, high-dimensional estimate would struggle.

Read through the same spectral lens as the machine-learning systems the distance-matrix observable comes from, the market never relaxes. Its delocalised exponent stays near 0.7 across all three crises with no quasi-multiplets and no shoulder, the signature of an un-relaxed, high-dimensional representation cloud rather than a geometry settled onto a low-dimensional sub-manifold. Where a learning system passes through a geometric phase transition and its distance matrix organises, the market does not, its distance matrix a permanently non-equilibrium object that a crisis drives further from equilibrium rather than toward a new steady state.

The three views are consistent and complementary, the systematic and the idiosyncratic halves of one cross section. The spectral collapse fires at the crash and the ranking responses follow over the next months, and the rate-driven utilities block that anchors the market-removed residual is the same one that leads the performance channel of the ranking transfer entropy.

The results give a consistent picture of what these diagnostics can identify and what they can predict. Crises are identifiable across the whole battery: the distance matrix loses dimension and rotates its eigenbasis, while the ranking chains lift their entropy production and shift their leadership. The individual market-stress events of the Covid decade are identifiable too, and which signal moves classifies the event, the arrow of time responding to a directional deleveraging like Archegos and the spectral concentration to a correlation shock like the Silicon Valley Bank failure, while brief symmetric shocks such as the Omicron scare leave little trace. Predictability is the harder half. Only the endogenously-building crisis, the 2008 buildup, is forecast in advance by the fragility signals. The exogenous 2020 crash and the single-session stress events are detected as they happen, not before. The diagnostics are thus a strong contemporaneous read of the cross section and only a partial early warning, informative ahead of time when a crisis assembles slowly enough to leave a fragility trail.

The approach suggests several natural extensions. The first is to add covariates to the ranking-chain dynamics. We treated the two chains as memoryless as a first approximation, and the systematic sector and firm-specific factors, together with the higher-order memory of the transitions, can be built in as exogenous drivers of the transition matrix. A state-dependent chain of this kind would add realism. Coupled to the persistence and leadership structure documented here, it points toward dynamic portfolio management, where a rank-based or transfer-entropy-informed strategy that buys the followers when the defensives lead connects these observables to stochastic portfolio theory [19, 20].

More broadly, the matrix-based formalism itself applies to portfolio construction and optimization. The effective dimension and correlation geometry of the distance matrix inform covariance estimation and risk budgeting, and the persistence, mixing time, and directed leadership of the ranking chains inform regime-conditioned allocation and rank-based tilts. The natural target is a dynamic portfolio-optimization problem whose objective adapts to the measured fragility and leadership state, with the fixed-size matrix observables serving as the state variables that carry the market history.

Two further refinements concern the early-warning reading of Section 4.7. The forecastable regime can be separated cleanly by conditioning on whether the correlation structure is already tightening, rather than pooling all crises into one ROC. The name-level attribution of Section 4.6 can be recomputed at a shorter lookback, trading a smaller large-cap universe for a tighter onset, and folded into a real-time count of how many names have already moved, a coincidence indicator alongside the fragility levels.
