

Portfolio Risk Bounds without Cross-Asset Return Covariances: Distributional Fields from Language-Model Representations

Marcus Gawronsky, Chun-Sung Huang
Department of Finance and Tax, University of Cape Town

August 2026

Abstract

Portfolio risk assessment ordinarily relies on reliable estimates of cross-asset return covariances, which are difficult to obtain in short, high-dimensional panels. We show that firm-level distribution-valued characteristics can instead provide one-sided certificates of portfolio risk. Under maintained links from characteristics to systematic exposures and from exposures to returns, multi-firm Wasserstein-2 dispersion yields a sharp upper bound on systematic portfolio variance and a corresponding bound for standardized returns. A weighted pairwise relaxation produces an objective that is convex under a checkable condition and requires marginal volatility scales but no cross-asset return covariances. With zero firm-specific slack, the common-map scale changes the certified variance reduction but not the normalized allocation, which depends only on observed information geometry. In a 52-firm panel from 2018–2022, an allocation constructed from Qwen3-Embedding-8B news representations lies between the 0.69th and 1.33rd in-sample variance percentiles across four prespecified capped portfolio populations; equal risk weighting lies between the 21.1st and 28.6th percentiles. The lower in-sample variance ranking relative to equal risk also appears across the reported frozen language-model representations. The framework therefore converts distribution-valued firm information into a coherent risk bound and an implementable allocation rule constructed without cross-asset return covariances.

1 Introduction

Mean–variance allocation requires a covariance matrix, yet that matrix is hardest to estimate in the settings where diversification matters most. An unrestricted covariance matrix for n assets contains $n(n+1)/2$ entries, while a demeaned return history of length T has rank at most $\min(T-1, n)$. Short histories therefore leave a portfolio manager with two linked problems: the strongest sample directions are noisy, and the optimizer is most sensitive to the weakest ones. Shrinkage and factor models reduce this burden by imposing structure (Ledoit and Wolf, 2004; Kelly et al., 2019), but their cross-asset information still originates in joint returns.

An alternative is to ask how much portfolio risk observable firm information can rule out before a return covariance matrix is estimated. We represent each firm by the

Figure 1: Observed information to portfolio choice. Solid arrows connect computed objects; the dashed arrow from observed W2 separation to the latent floor is the maintained transmission restriction. Blue denotes observed objects, orange latent and certificate objects, green the risk bound, and purple the allocation decision.

distribution of its article embeddings and use quadratic optimal transport to compare those distributions. When two information distributions are sufficiently different, maintained restrictions linking information to systematic exposures imply that the firms’ latent risks cannot be perfectly aligned. The resulting separation certifies a diversification benefit relative to perfect positive dependence.

For a standardized long-only portfolio with normalized risk weights q , the headline result takes the form

$$\text{Var}(R_q) \leq 1 - \mathcal{C}(q).$$

The value 1 is the variance benchmark under perfect positive dependence, and $\mathcal{C}(q)$ is the amount that the observed information geometry certifies away. A larger certificate therefore tightens the admissible upper bound on portfolio risk. It does not estimate the covariance matrix.

The same distribution-valued representation has generated related financial objects at neighbouring levels of aggregation. At the pairwise level, Gawronsky and Huang (2026a) derive a covariance envelope from Wasserstein separation. At the cross-sectional level, Gawronsky and Huang (2026b) use target-anchored Wasserstein barycentric reconstruction to form a barycentric interaction field. The contribution here is at the portfolio level: it aggregates information-derived separation within one coherent joint exposure law and turns the resulting variance bound into a decision rule. The construction below is self-contained.

Let C_i denote firm i ’s observed characteristic law and let P_i denote its latent exposure law in factor-risk coordinates. Empirically, C_i is the distribution of the firm’s article embeddings. The quadratic Wasserstein distance $W_2(C_i, C_j)$ is the minimum root-mean-square displacement required to match the two article clouds. It therefore measures how much semantic mass must be rearranged to make the observed information distributions coincide. The latent law P_i describes systematic exposure rather than text, so C_i and P_i need not share units and one does not identify the other directly.

Three maintained links carry the argument from observed information to portfolio risk. A common information-to-exposure map prevents distinct information states from collapsing into identical systematic exposures, while firm-specific slack permits bounded departures from that common map. A coherent joint law ensures that all pairwise exposure relations can coexist within the same portfolio. A return bridge then connects systematic exposure variance to standardized total returns. The text determines the observed geometry; it does not identify these transmission restrictions.

For a common carrier constant $L > 0$ and firm-specific slack radii τ_i , the observable pairwise floor is

$$\ell_{ij} = \left[L^{-1} W_2(C_i, C_j) - \tau_i - \tau_j \right]_+.$$

This floor is the exposure separation that remains after allowing for common distortion and the two firms’ deviations from the common map. The positive part records that the observed distance may be too small to certify any separation once slack is deducted. The portfolio certificate aggregates these floors using normalized risk weights for a long-only portfolio:

$$\mathcal{C}(q) = \frac{1}{2} \sum_i \sum_j q_i q_j \ell_{ij}^2.$$

Separation between a pair contributes only when the portfolio holds both firms, and contributes more when their joint portfolio weight is larger. If the exposure marginals belong to one coherent joint law and the maintained carrier and slack restrictions hold, systematic portfolio variance is bounded by weighted marginal second moments less $\mathcal{C}(q)$. The standardized return bridge then gives the headline bound above. Observed differences between firms therefore restrict the joint risk configurations that remain admissible.

Investors choose capital weights rather than normalized risk weights. For capital weights x_i and marginal volatility scales σ_i , define $A(x) = \sum_i x_i \sigma_i$ and $q_i(x) = x_i \sigma_i / A(x)$. The corresponding raw-return certificate is

$$\text{Var}(R_x) \leq A(x)^2 \{1 - \mathcal{C}(q(x))\}.$$

Minimizing this upper bound yields an information-certified portfolio without an expected-return input. Compactness of the feasible long-only set supplies existence of a minimizer, while a directly checkable condition on the observed distance matrix makes the standardized objective convex.

The empirical exercise keeps construction separate from evaluation. The canonical zero-slack implementation, which we call the news-only allocation, is formed from observed W2 geometry without using cross-asset return covariance and is evaluated only afterwards on the full-sample standardized covariance matrix. Across four prespecified capped long-only reference populations, between 0.69% and 1.33% of feasible portfolios have variance no greater than the news-only allocation. The corresponding share for equal risk weights—the inverse-volatility capital benchmark expressed in normalized risk-weight coordinates—lies between 21.1% and 28.6%. These rankings are descriptive and in-sample; they illustrate the allocation implied by the maintained model rather than forecast out-of-sample performance.

The paper makes three contributions. First, it derives a coherent portfolio variance bound in a sharp multi-firm form and supplies the computationally simpler weighted pairwise relaxation used by the decision rule. Second, it shows that when firm-specific slack is zero, the common carrier scale changes the certified variance reduction but not the normalized allocation, which is determined by the observed information geometry. Third, in a 52-firm in-sample exercise, it reports how the allocation’s conventionally evaluated variance ranks under four prespecified feasible-portfolio laws.

The argument proceeds from identification to decision and then to descriptive evaluation. Section 2 positions the contribution in structured covariance, factor-risk, and textual-characteristic research. Section 3 defines the observed, latent, and coherent portfolio objects and derives the information-certified variance bound. Section 4 turns the pairwise certificate into a decision rule. Sections 5 and 6 describe the data and report the in-sample variance ranking. Section 7 discusses what the results establish and where their boundaries lie before Section 8 concludes.

2 Related literature

Markowitz portfolio choice makes covariance the central input to minimum-variance allocation (Markowitz, 1952). In short or high-dimensional return panels, however, the sample covariance can be unstable or singular. Regularization improves that input by replacing part of its sampling variation with a structured target (Ledoit and Wolf, 2004). Such methods make covariance estimation more reliable, but they still solve the portfolio problem by first estimating joint return risk.

The alternative developed here changes the source and form of the risk information. Under a maintained information-to-exposure bridge, observable separation between firms' information distributions rules out part of the perfect-positive-dependence benchmark without estimating every covariance entry. The resulting object is a one-sided bound that can be evaluated at feasible portfolio weights and then minimized. It is therefore a certificate about admissible joint risk configurations, not a replacement point estimate for the covariance matrix. This distinction determines how the factor, distributional, and textual literatures enter the argument.

Factor models clarify the latent object that covariance summarizes. The CAPM represents systematic covariance through scalar market loadings (Sharpe, 1964), whereas APT and approximate-factor models use vector or expanding factor structures (Ross, 1976; Chamberlain and Rothschild, 1983; Bai and Ng, 2002). Characteristic-based models then use observable firm attributes to organize loadings and expected returns (Rosenberg, 1974; Connor and Linton, 2007; Connor et al., 2012; Kelly et al., 2019). These approaches explain how systematic exposures generate dependence, but an observed characteristic is not itself an exposure or covariance estimate.

Distribution-valued characteristics replace a single firm descriptor with a probability law and use quadratic transport to compare those laws. For two exposure laws, the minimum expected squared displacement also determines the maximum systematic covariance permitted by their marginals. Using this identity, Gawronsky and Huang (2026a) derive a pairwise covariance envelope from observable distributional separation under maintained information-to-exposure restrictions. That result establishes the pairwise level of the argument: observed geometry can restrict how closely two latent systematic risks align.

At the cross-sectional level, Gawronsky and Huang (2026b) develop target-anchored Wasserstein barycentric reconstruction. The resulting distributional spanning weights form a target-specific barycentric interaction field that enters exposure adjustment. That cross-sectional system organizes firm-level exposure adjustment rather than the risk of a portfolio assembled from those firms. The two studies therefore supply neighbouring pairwise and cross-sectional implications of distributional geometry, but neither resolves portfolio aggregation.

Portfolio risk adds a joint-compatibility requirement. Pairwise optimal couplings need not be the pairwise marginals of any single joint exposure law, so separately attainable covariance envelopes cannot simply be stacked into a coherent portfolio risk configuration. The portfolio-level step retains one joint law for all exposure marginals and uses its weighted dispersion to deduct a certified amount from worst-case systematic variance. The weighted sum of squared Wasserstein distances provides a computational relaxation of that multi-firm object, while the sharp form preserves the common coupling needed for coherent portfolio risk.

Textual finance establishes that documents contain financially relevant information. Prior studies map text into sentiment and disclosure measures, return forecasts, predictive factors, and learned pricing objects (Tetlock, 2007; Loughran and McDonald, 2011;

Gentzkow et al., 2019; Ke et al., 2019; Cong et al., 2024; Distaso et al., 2024; Wang et al., 2025). Their primary targets are expected returns, factors, or pricing rather than a coherent bound on cross-asset portfolio risk.

Modern encoders make the distributional approach empirically feasible by representing each document as a vector (Reimers and Gurevych, 2019; Zhang et al., 2025). Word Mover’s Distance provides an NLP precedent for using optimal transport to compare empirical distributions of embeddings (Kusner et al., 2015). Retaining a firm’s article embeddings as an empirical distribution preserves within-firm heterogeneity that a single pooled vector would suppress. In the present setting, those embeddings measure observed information geometry; they do not measure latent exposure or covariance directly. The carrier-and-slack restrictions provide the maintained link from that measurement layer to exposure separation.

Taken together, portfolio theory supplies the decision problem, factor and distributional models identify the latent risk objects and pairwise restrictions, and text encoders supply observable information geometry. What remains absent is a portfolio-level bridge from that geometry to a risk bound supported by one coherent exposure law. The theory therefore begins by separating observed characteristic laws, latent exposure laws, and their maintained transmission before deriving the coherent portfolio bound and its decision rule.

3 Model and information-certified variance bound

The systematic exposures that generate portfolio risk are latent, whereas the paper observes firms’ information. The model therefore separates three roles: an observed information law, a latent systematic-exposure law, and a maintained transmission restriction that connects the two without equating them. It then places all latent exposures under one coherent joint law so that pairwise restrictions can support an n -asset portfolio statement.

Let $i \in \{1, \dots, n\}$ index assets. The observed object records the distribution of firm i ’s information. Formally, X_i is an observable characteristic draw taking values in a separable metric space $\mathcal{X}$, and its law C_i is the probability distribution of the firm’s row-normalized article embeddings. The latent object records the corresponding systematic exposure. Let B_i denote that exposure in a real Hilbert space $\mathcal{H}$. The exposure model is

$$B_i = u_i(X_i), \quad P_i = \mathcal{L}(B_i), \quad (1)$$

where the measurable map u_i captures the firm’s information-to-exposure mapping and P_i is the resulting latent exposure law. Thus C_i and P_i are distinct laws and need not use the same metric units.

The maintained transmission restriction supplies the link between these two spaces. Its common component is a measurable carrier $t : \mathcal{X} \rightarrow \mathcal{H}$. It is L -antilipschitz:

$$d_{\mathcal{H}}(t(x), t(y)) \geq L^{-1} d_{\mathcal{X}}(x, y), \quad L > 0. \quad (2)$$

Each firm-specific map remains within a synchronous slack radius:

$$d_{\mathcal{H}}(u_i(x), t(x)) \leq \tau_i \quad \text{for every } x, \quad \tau_i \geq 0. \quad (3)$$

The antilipschitz restriction prevents economically distinct information states from collapsing into identical systematic exposures, while τ_i permits firm-specific information-to-exposure mismatch. Together, these restrictions translate observed information distance into a lower bound on exposure separation rather than an equality or a covariance estimate.

Pairwise exposure restrictions do not by themselves define portfolio risk. To aggregate them, let J be one coherent joint law for $(B_1, \dots, B_n)$ with coordinate marginals P_i . For normalized risk weights $q_i \geq 0$ satisfying $\sum_i q_i = 1$, define

$$v_i = \mathbb{E}_J \|B_i\|^2, \quad V_{\text{sys}}(q) = \mathbb{E}_J \left\| \sum_i q_i B_i \right\|^2.$$

The same J governs every cross term, so the induced covariance matrix is positive semidefinite. This requirement rules out assembling a portfolio from mutually incompatible pairwise optimal couplings.

With the observed and latent objects linked and joint coherence imposed, the next subsections derive observable pairwise floors, aggregate them into a conservative portfolio certificate, sharpen that certificate with a multi-firm object, and finally connect systematic exposure risk to returns.

This section turns the model's maintained link into a portfolio-risk statement. It first asks what exposure separation each observed pair can certify, then aggregates those pairwise floors under the coherent joint law. The resulting credit lowers the benchmark in which no cross-asset separation can be certified.

3.1 Observable pairwise floors

The carrier and slack restrictions first yield the minimum exposure separation supported by each pair's observed information distance. For assets i and j , define

$$\ell_{ij} := \left[L^{-1} W_2(C_i, C_j) - \tau_i - \tau_j \right]_+, \quad [a]_+ := \max\{a, 0\}. \quad (4)$$

The antilipschitz carrier first retains at least the fraction L^{-1} of the observed W2 separation. The triangle inequality then deducts the two slack radii. Truncation at zero preserves the nonnegative lower bound, giving

$$\ell_{ij} \leq W_2(P_i, P_j). \quad (5)$$

Every term in (4) therefore has a distinct role: $W_2(C_i, C_j)$ is observed geometry, L controls common distortion, and the τ_i terms absorb asset-specific departures from the common carrier. In the empirical application, $W_2(C_i, C_j)$ is the least root-mean-square displacement required to align the two firms' information distributions. A positive ℓ_{ij} rules out exposure laws that are closer than this floor; a zero floor means only that the maintained restrictions certify no positive separation for that pair.

The candidate portfolio credit weights each pairwise floor by the extent to which both assets enter a normalized long-only portfolio:

$$\mathcal{C}(q) := \frac{1}{2} \sum_i \sum_j q_i q_j \ell_{ij}^2. \quad (6)$$

The factor one half compensates for counting both ordered pairs (i, j) and (j, i) . Because diagonal distances are zero, this is also $\sum_{i < j} q_i q_j \ell_{ij}^2$. The ordered-pair sum is portfolio-specific: separation between two assets contributes only to the extent that both are held. Conditional on the declared carrier and slack parameters, $\mathcal{C}(q)$ is computed from observed information geometry rather than a return covariance matrix.

3.2 From floors to coherent portfolio variance

Pairwise floors constrain individual asset pairs, but portfolio risk is a joint object. To aggregate the floors without combining incompatible pairwise couplings, apply the weighted Hilbert-space polarization identity under the same joint law J :

$$\left\| \sum_i q_i B_i \right\|^2 = \sum_i q_i \|B_i\|^2 - \frac{1}{2} \sum_i \sum_j q_i q_j \|B_i - B_j\|^2. \quad (7)$$

Taking expectations under the coherent law J is valid when the pairwise inner products are integrable. For each pair, the realized J -marginal is an admissible coupling of P_i and P_j . Its expected squared displacement is therefore no smaller than $W_2^2(P_i, P_j)$, which in turn is no smaller than ℓ_{ij}^2 by (5). Substituting those lower bounds into the subtracted term of (7) yields the main result.

Theorem 1 (Information-certified coherent portfolio variance). *Suppose the common carrier satisfies (2), the asset-specific maps satisfy (3), the exposure laws are marginals of one joint law J , and all pairwise inner products are integrable. Then every normalized long-only portfolio obeys*

$$V_{\text{sys}}(q) \leq \sum_i q_i v_i - \mathcal{C}(q). \quad (8)$$

The theorem is an upper bound on systematic portfolio variance, not a point estimate of a covariance matrix. Its benchmark $\sum_i q_i v_i$ is the weighted marginal second-moment term that would remain if no cross-asset separation could be certified. The observable characteristic laws deduct $\mathcal{C}(q)$ from that benchmark. Larger distances tighten the deduction; larger distortion or slack weakens it. In finance terms, $\mathcal{C}(q)$ is the diversification relief that the observed information can certify under the maintained transmission model.

The result is conservative in two specific ways, which the next subsection makes precise and addresses jointly. Pairwise optimal couplings need not all coexist inside one joint law, so the weighted pairwise floor understates the separation any coherent joint exposure law must incur. Equation (6) also deducts each pair's two slack radii separately and truncates the result pair by pair, discarding every pair whose observed separation falls below its combined radius.

3.3 The sharp multi-firm certificate

The pairwise credit relaxes a single multi-firm object. That object measures the least total separation compatible with all observed characteristic laws under one common coupling. We refer to it as weighted multi-firm transport dispersion; for observed characteristic laws, the formal object below is weighted characteristic dispersion. Stating it directly tightens the deduction, and its two-asset case is exactly the pairwise covariance envelope of Gawronsky and Huang (2026a), so the sharpening does not introduce a second theory.

Fix normalized risk weights q as above. Within $\mathcal{D}_q$, these weights are inputs: the infimum varies the coherent common coupling while holding q fixed. Only the portfolio-choice problem in Section 4 later treats q as a decision variable.

Definition 1 (Weighted characteristic dispersion). Let Π denote the set of joint laws on $\mathcal{X}^n$ whose i th marginal is C_i . For characteristic laws $C_1, \dots, C_n$ on $(\mathcal{X}, d_{\mathcal{X}})$ and $(X_1, \dots, X_n) \sim \gamma$,

$$\mathcal{D}_q(C_1, \dots, C_n) := \inf_{\gamma \in \Pi} \mathbb{E}_{\gamma} \left[\sum_{i < j} q_i q_j d_{\mathcal{X}}(X_i, X_j)^2 \right]. \quad (9)$$

The infimum is what makes the quantity conservative. It asks how close the laws could be under their most favourable common coupling, not how separated one selected matching makes them appear. Its units are squared characteristic distance, and its value depends on the ground metric and on q .

Two facts locate (9) against objects already in play. First, restricting a common coupling to any pair leaves an admissible coupling of that pair, whose expected squared displacement is therefore at least $W_2^2(C_i, C_j)$. Summing gives

$$\mathcal{D}_q(C_1, \dots, C_n) \geq \sum_{i < j} q_i q_j W_2^2(C_i, C_j). \quad (10)$$

The weighted pairwise sum is thus a computable lower bound on the multi-firm object, which is the inequality (6) exploits. It can be built once from pairwise distances, but it does not retain the full restriction that all asset marginals share one coupling. Second, on a Hilbert space the same value has a free-centre Wasserstein barycentre representation: for exposure laws with finite second moments,

$$\mathcal{D}_q(P_1, \dots, P_n) = \inf_Q \sum_i q_i W_2^2(P_i, Q), \quad (11)$$

where Q ranges over finite-second-moment laws on $\mathcal{H}$. For fixed q , only Q varies. This shares the barycentric geometry of Gawronsky and Huang (2026b) but is not its target-anchored Wasserstein barycentric reconstruction; that problem fixes i and its alignments and varies w_i to form $W^\flat$. Proposition 3 states this in the appendix. Only equality of the two infimum values is used; neither an optimal barycentre nor an optimal joint plan is assumed to exist.

The two-asset case recovers the pairwise foundation exactly.

Proposition 1 (Two-asset nesting). *Let $n = 2$ and suppose some coherent joint law attains the dispersion minimum for P_1, P_2 . Then the systematic portfolio variance it attains is*

$$q_1 v_1 + q_2 v_2 - q_1 q_2 W_2^2(P_1, P_2). \quad (12)$$

Substituting $n = 2$ into the dispersion definition gives $\mathcal{D}_q(P_1, P_2) = q_1 q_2 W_2^2(P_1, P_2)$. Weighted polarization then yields (12).

Equation (12) is the covariance-envelope correction of Gawronsky and Huang (2026a) written in portfolio form. The multi-firm construction extends that pairwise foundation to a coherent joint exposure law.

The dispersion in (9) remains measured in observed characteristic units, whereas the variance bound concerns latent exposure units. The same carrier and slack restrictions transfer the whole multi-firm object between these spaces rather than treating each pair separately. Aggregate the firm-specific mismatch through the weighted root-mean-square slack radius

$$\tau_q := \left(\sum_i q_i \tau_i^2 \right)^{1/2}. \quad (13)$$

Theorem 2 (Characteristic-to-exposure dispersion). *Suppose the common carrier satisfies (2) and the asset-specific maps satisfy (3). Then*

$$\sqrt{\mathcal{D}_q(P_1, \dots, P_n)} \geq \left[L^{-1} \sqrt{\mathcal{D}_q(C_1, \dots, C_n)} - \tau_q \right]_+. \quad (14)$$

For the transfer proof, write $T_i := t_{\#} C_i$ and abbreviate $\mathcal{D}_q(C_1, \dots, C_n)$, $\mathcal{D}_q(P_1, \dots, P_n)$, and $\mathcal{D}_q(T_1, \dots, T_n)$ by $\mathcal{D}_q(C)$, $\mathcal{D}_q(P)$, and $\mathcal{D}_q(T)$. The antilipschitz inequality implies, after pushing any coupling of the C_i through t ,

$$\sqrt{\mathcal{D}_q(C)} \leq L \sqrt{\mathcal{D}_q(T)}.$$

The synchronous coupling $(u_i(X_i), t(X_i))$ gives

$$W_2(P_i, T_i) \leq \tau_i.$$

The weighted product-space stability inequality then yields

$$\left| \sqrt{\mathcal{D}_q(P)} - \sqrt{\mathcal{D}_q(T)} \right| \leq \left(\sum_i q_i W_2^2(P_i, T_i) \right)^{1/2} \leq \tau_q.$$

Combining the last two displays gives

$$\sqrt{\mathcal{D}_q(P)} \geq L^{-1} \sqrt{\mathcal{D}_q(C)} - \tau_q.$$

Both sides of the left-hand inequality are nonnegative, so taking the positive part proves (14). Thus, even under the most favourable common coupling of the observed laws, the carrier preserves a minimum amount of latent exposure dispersion after one aggregate allowance for firm-specific mismatch.

Squaring this transferred floor gives the sharp observable credit

$$\mathcal{C}^\sharp(q) := \left[L^{-1} \sqrt{\mathcal{D}_q(C_1, \dots, C_n)} - \tau_q \right]_+^2. \quad (15)$$

Theorem 3 (Sharp information-certified portfolio variance). *Under the hypotheses of Theorem 1, every normalized long-only portfolio obeys*

$$V_{\text{sys}}(q) \leq \sum_i q_i v_i - \mathcal{C}^\sharp(q). \quad (16)$$

The proof is the following chain, where the first inequality uses the dispersion infimum and the second uses Theorem 2:

$$\begin{aligned} V_{\text{sys}}(q) &= \sum_i q_i v_i - \mathbb{E}_J \left[\sum_{i < j} q_i q_j \|B_i - B_j\|^2 \right] \\ &\leq \sum_i q_i v_i - \mathcal{D}_q(P) \\ &\leq \sum_i q_i v_i - \mathcal{C}^\sharp(q). \end{aligned}$$

No attaining plan is needed for this bound. The theorem therefore tightens the systematic-risk cap by preserving joint compatibility across all assets instead of replacing the infimum over common couplings with a sum of pairwise infima.

Proposition 2 (Envelope exactness). *If some coherent joint law attains the dispersion minimum for $P_1, \dots, P_n$, then $\sum_i q_i v_i - \mathcal{D}_q(P_1, \dots, P_n)$ is the greatest systematic portfolio variance attainable across coherent joint laws.*

An attaining joint law realizes $\mathcal{D}_q(P)$, while every other coherent law has dispersion at least that infimum. Consequently, none can have greater systematic variance than the value stated in the proposition. This exactness concerns the variance envelope generated by the fixed exposure marginals and an attaining coherent law; it does not identify a return covariance matrix from text.

Theorem 3 dominates Theorem 1 in two independent respects. Equation (10) makes the multi-firm dispersion at least the weighted pairwise sum, and (15) subtracts one aggregate radius where (4) subtracts $\tau_i + \tau_j$ from every pair. Under a common radius τ the second effect alone replaces a deduction of 2τ per pair by a single τ . Neither improvement needs new data: both use the same observed W2 geometry and the same declared (L, τ) .

The direction of the improvement is substantive. A larger credit is a tighter variance bound, and the sharp form replaces the pairwise relaxation with the coherent multi-firm dispersion while applying slack once at the aggregate level. The pairwise credit remains the decision form because it is a quadratic function of q built once from the observed distance matrix, whereas evaluating $\mathcal{D}_q$ at a candidate q requires solving an inner free-centre barycentre problem. The later portfolio search varies q outside those fixed- q evaluations; it is not part of the definition of $\mathcal{D}_q$. The empirical exercise therefore reports the pairwise relaxation while the sharp theorem records the coherent multi-firm benchmark against which that computational relaxation is judged.

3.4 Return bridge and residual sensitivity

The results so far bound latent systematic exposure risk, not observed return variance. To obtain a total-return statement, standardize each asset to unit marginal variance and decompose its return into systematic and residual components. This return bridge is a maintained restriction rather than a consequence of the information geometry.

Assumption 1 (Return bridge). Each standardized return splits as $R_i = S_i + \varepsilon_i$ into a scalar systematic component S_i carrying the exposure geometry and a residual ε_i . Write $v_i = \text{Var}(S_i)$. The residual vector is cross-orthogonal to the systematic component:

$$\text{Cov}(S_i, \varepsilon_j) = 0 \quad \text{for every } i \text{ and } j.$$

For risk weights q , set $S_q := \sum_i q_i S_i$ and write

$$\text{Var}(R_q) = \text{Var}(S_q) + \mathcal{R}(q), \quad \mathcal{R}(q) := \sum_i \sum_j q_i q_j \text{Cov}(\varepsilon_i, \varepsilon_j).$$

Unit marginal return variance and zero systematic-residual covariance give $\text{Var}(\varepsilon_i) = 1 - v_i$. Zero cross-residual covariance is the benchmark; more generally, the excess residual contribution is bounded by a declared $\delta \geq 0$.

Under zero cross-residual covariance, the systematic certificate and the diagonal residual terms give

$$\begin{aligned} \text{Var}(R_q) &\leq \sum_i q_i v_i - \mathcal{C}(q) + \sum_i q_i^2 (1 - v_i) \\ &= 1 - \mathcal{C}(q) - \sum_i q_i (1 - q_i) (1 - v_i) \\ &\leq 1 - \mathcal{C}(q). \end{aligned} \tag{17}$$

The first line combines the systematic certificate with diagonal residual variance. The equality isolates the additional diversification relief supplied by asset-specific residual

risk. Long-only normalization gives $q_i(1 - q_i) \geq 0$, so the final inequality discards that nonnegative relief and leaves the simpler $1 - \mathcal{C}(q)$ certificate. With residual contamination, retain the sensitivity wrapper

$$\text{Var}(R_q) \leq 1 - \mathcal{C}(q) + \delta. \quad (18)$$

Here δ is a portfolio residual-covariance budget used for sensitivity analysis, not an estimated structural parameter. To express the standardized result as a capital-allocation bound, separate capital weights from shares of the perfect-dependence volatility budget. For long-only capital weights $x_i \geq 0$ with $\sum_i x_i = 1$ and positive marginal scales σ_i , define

$$A(x) := \sum_i x_i \sigma_i, \quad q_i(x) := \frac{x_i \sigma_i}{A(x)}. \quad (19)$$

Here $A(x)$ is the portfolio volatility under perfect positive dependence. The normalized weight $q_i(x)$ is asset i 's share of that benchmark. Thus x_i are capital weights whereas q_i are risk-budget shares; in particular, $x_i \propto 1/\sigma_i$ implies $q_i = 1/n$. Multiplying (18) by $A(x)^2$ yields

$$\text{Var}(R_x) \leq A(x)^2 \{1 - \mathcal{C}(q(x)) + \delta\}. \quad (20)$$

This is the financial interpretation of the certificate: $A(x)^2$ is the perfect-dependence benchmark, while $A(x)^2 \mathcal{C}(q(x))$ is the amount of raw systematic variance ruled out by the observed information geometry under the maintained transmission model. The additive term $A(x)^2 \delta$ makes residual sensitivity explicit. Equation (20) is therefore a decision input rather than an estimated covariance model. At the benchmark $\delta = 0$, Section 4 turns this certified risk bound into a portfolio rule by minimizing it over a feasible allocation set.

4 Portfolio choice under the certificate

The preceding section establishes how much portfolio variance the observed information geometry can certify under the maintained transmission model. The investor's task is now to turn that risk statement into an allocation rule without treating the bound as an estimated covariance matrix. At the benchmark with $\delta = 0$, the natural decision is to choose the feasible capital allocation with the smallest certified upper bound in (20).

Let $\mathcal{W}$ be a nonempty compact subset of the long-only simplex, possibly incorporating upper-weight, sector, or turnover constraints. Each $x \in \mathcal{W}$ is a vector of capital weights, whereas $q(x)$ records the corresponding normalized shares of the perfect-positive-dependence volatility budget defined in (19). Define the certified-variance objective

$$\text{CV}(x) := A(x)^2 \{1 - \mathcal{C}(q(x))\}. \quad (21)$$

The information-certified portfolio solves

$$x^* \in \arg \min_{x \in \mathcal{W}} \text{CV}(x). \quad (22)$$

Equation (22) is a minimum-risk problem. Expected returns do not enter its objective, constraints, or identifying argument. The objective is economically appropriate because it minimizes a certified risk cap rather than a point estimate of otherwise unknown portfolio variance.

The two components of (21) make the allocation trade-off explicit. The term $A(x)^2$ is the variance benchmark under perfect positive dependence, so reducing $A(x)$ lowers the

same marginal-volatility benchmark used by an inverse-volatility portfolio. The deduction $A(x)^2 \mathcal{C}(q(x))$ rewards allocations whose information distributions certify that their latent risks cannot all be aligned. Inverse volatility is therefore the cleanest empirical benchmark: it uses the first channel but not the second.

The first mathematical requirement is that this decision rule actually has a solution.

Theorem 4 (Existence of a certified-variance minimizer). *Every nonempty compact feasible subset $\mathcal{W}$ of the long-only simplex admits a minimizer of the continuous objective (21), and the pointwise variance certificate holds at that minimizer.*

For fixed distance and marginal-scale inputs, CV is continuous on $\mathcal{W}$. The set is nonempty and compact, so Weierstrass gives a minimizer. The pointwise certificate in (20) then holds at that minimizer.

Existence makes the rule well defined on any compact feasible set; curvature is a separate guarantee about how the standardized problem can be solved. That curvature is a property of the observed geometry rather than an assumption about returns. For a symmetric zero-diagonal matrix d , conditional negative definiteness means

$$\sum_i \sum_j u_i u_j d_{ij}^2 \leq 0 \quad \text{whenever} \quad \sum_i u_i = 0.$$

Theorem 5 (Certificate convexity). *If the pairwise floor matrix ℓ is conditionally negative definite, then $q \mapsto 1 - \mathcal{C}(q)$ is convex along mixtures of normalized risk weights.*

For every tangent direction with $\mathbf{1}^\top u = 0$,

$$\frac{d^2}{dt^2} \mathcal{C}(q + tu) = u^\top \ell^2 u \leq 0.$$

Hence $\mathcal{C}$ is concave and $1 - \mathcal{C}$ is convex on the simplex.

By Schoenberg's criterion the condition holds exactly when the double-centred matrix $-\frac{1}{2}(I - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)\ell^2(I - \frac{1}{n}\mathbf{1}\mathbf{1}^\top)$ is positive semidefinite, equivalently when the floors embed isometrically in a Hilbert space. It is therefore checkable directly from the reported W2 matrix, without returns and without an estimated parameter, and it holds for the frozen matrix used here. Under this condition, minimizing the standardized certificate over a convex feasible set is a convex program.

A third guarantee concerns sensitivity to the carrier scale rather than existence or curvature. In the zero-slack boundary case, the carrier constant drops out of the normalized decision.

Corollary 1 (Carrier invariance of the normalized allocation). *Let $\tau_i = 0$ for every asset. Then $\ell_{ij} = L^{-1}W_2(C_i, C_j)$ and*

$$\mathcal{C}(q) = \frac{1}{2L^2} q^\top W_2^2 q, \tag{23}$$

so for any $L > 0$ and any feasible set $\mathcal{Q}$ of normalized risk weights,

$$\arg \max_{q \in \mathcal{Q}} \mathcal{C}(q) = \arg \max_{q \in \mathcal{Q}} q^\top W_2^2 q.$$

The factor L^{-2} is positive, so scaling the objective does not change its maximizers. Under zero slack, L determines how much variance the certificate deducts but not which normalized risk allocation achieves the largest deduction. That allocation is determined by the observed W2 geometry.

The carrier-invariance statement concerns normalized risk weights q , which are shares of the perfect-dependence volatility budget, not the capital weights x held by the investor. The raw objective retains L through the interaction between $A(x)^2$ and $\mathcal{C}(q(x))$, so converting an invariant risk allocation into capital still requires the marginal scales σ_i . When slack is nonzero, $\tau_i + \tau_j$ enters the floor additively and the truncation depends jointly on L and τ . Together, the existence, curvature, and carrier-invariance results turn the certificate into an implementable decision rule while keeping its dependence on the maintained inputs explicit. Section 5 next constructs the zero-slack allocation from observed news geometry, and Section 6.2 evaluates its realized variance against conventional portfolio benchmarks.

5 Empirical design and data

The information-certified portfolio in Section 4 is the theoretical class of allocations that minimize the certified variance bound. The empirical exercise implements its zero-slack, standardized-asset specialization; throughout the empirical sections, the resulting canonical implementation is the news-only allocation. At this boundary, the carrier scale changes the size of the variance certificate but not the normalized allocation selected from the observed information geometry. With unit marginal scales, $A(x) = 1$ and $q = x$, so minimizing the certified variance objective is equivalent to maximizing the pairwise certificate over normalized weights. Implementing the general raw-capital objective would instead require the marginal scales in (19). The design next defines the reference populations used to evaluate the standardized allocation and constructs the news geometry that enters the decision. Returns assess the news-only allocation only after the decision has been made.

5.1 Directional hypothesis and reference-population estimand

The directional hypothesis is that the news-only allocation lies in the lower tail of conventional variance among feasible portfolios with comparable concentration. The theory motivates this direction under the maintained return bridge, but it does not determine a percentile or imply out-of-sample performance. The news-only allocation is

$$q^{\text{news}} \in \arg \max_{q \geq 0, \mathbf{1}^\top q = 1} \frac{1}{2} q^\top W_2^2 q.$$

It is constructed from the observed W_2 geometry before the return covariance enters the evaluation.

Let

$$V(q) := q^\top \hat{\Sigma}_R q$$

be standardized full-sample return variance. For each reference population $\mathcal{G}_k$, define the lower-tail percentile

$$p_k := \Pr_{q \sim \mathcal{G}_k} \{V(q) \leq V(q^{\text{news}})\}, \quad \hat{p}_k := B^{-1} \sum_{b=1}^B \mathbf{1}\{V(q_k^{(b)}) \leq V(q^{\text{news}})\}, \quad B = 20\,000.$$

The estimand p_k is the share of portfolios from reference population $\mathcal{G}_k$ whose variance is no greater than the news-only allocation's. Accordingly, a smaller $\hat{p}_k$ means that fewer reference portfolios achieve equally low or lower variance, placing the candidate nearer the bottom of the conventional-variance distribution. This quantity is a Monte Carlo estimate of a descriptive reference-population percentile, not a classical p-value, and the analysis imposes no rejection threshold.

Each $\mathcal{G}_k$ starts with a symmetric Dirichlet draw on the long-only simplex, clips every weight at its cap, and renormalizes until the allocation is feasible. The four (α, cap) pairs are

$$(1, 12.5\%), \quad (1, 15\%), \quad (0.8, 15\%), \quad (0.5, 15\%).$$

The first two populations isolate cap sensitivity. The effective number of names is

$$N(q) := \left(\sum_i q_i^2 \right)^{-1}.$$

The $\alpha = 0.8$ law is calibrated so that its mean $N(q)$ matches the candidate’s effective number of names, while $\alpha = 0.5$ supplies a more concentrated comparison. The retained populations are transformations of Dirichlet draws rather than draws from a truncated Dirichlet law.

These laws define comparison populations rather than portfolio strategies that an investor would implement directly. Their common feasible set is fully invested, long-only, and subject to a single-name cap, a recognizable portfolio-constraint template even though the exact thresholds are stylized rather than rules of a named mandate. The 12.5% cap rules out portfolios supported on fewer than eight names; the 15% cap relaxes that minimum to seven. Changing the cap tests sensitivity to the admissible largest position, while changing α alters typical concentration within the capped simplex. Practical mandates may additionally constrain sectors, liquidity, turnover, or tracking error, none of which these reference laws reproduce.

The named strategy benchmarks answer a different question. Equal normalized risk weights set $q_i = 1/N$ and, through (19), correspond to inverse-volatility capital weights. They use marginal volatility but not cross-asset covariance. The ex post sample GMV instead uses the full return covariance and supplies the covariance-informed in-sample optimum. Thus the reference populations locate the news-only allocation within declared feasible sets, whereas the named benchmarks give its variance an economically familiar scale.

5.2 Returns, news, and Wasserstein construction

The analytical sample follows source, restriction, and final-sample order. Daily simple returns are Yahoo Finance adjusted-close ratios minus one. These are raw rather than excess returns; no risk-free series is subtracted. Exact date alignment supplies 1207 common observations from 2018-03-19 through 2022-12-30, with missing dates removed rather than imputed.

Nasdaq’s per-symbol news archive supplies firm articles from 2018 through 2022. The analysis applies one ticker-indexed retrieval rule and retains dated article bodies across the prespecified universe. This construction is auditable, but the paper neither establishes comprehensive coverage relative to proprietary news archives nor treats the ticker assignment as manually validated article-level entity annotation. The annual coverage screen and balanced-cloud rule then form equal-sized empirical article distributions for the canonical 2022 geometry. Eligible articles are ordered deterministically by URL hash before the common cloud size is imposed, so news volume does not enter the distance merely through unequal empirical support. The annual cloud-size ladder appears in Section C.

Return alignment drops WBA and leaves 52 firms, and each series is standardized over the common panel before $\hat{\Sigma}_R$ is formed. This is a coverage-screened survivor panel rather than historical index membership.

An embedding model maps an article body to a fixed-dimensional numerical vector and is trained to place semantically related documents nearer in that space. The primary representation independently encodes each article with the frozen, 4,096-coordinate Qwen3-Embedding-8B bi-encoder (Zhang et al., 2025). It is obtained through OpenRouter’s OpenAI-compatible embeddings API as `qwen/qwen3-embedding-8b`; rows are normalized. This frozen representation is the cross-paper canonical model. Rather than average a firm’s article vectors into one point, the design treats its row-normalized cloud as an equal-mass empirical distribution. Balanced quadratic transport then pairs articles across two equal-sized clouds to minimize their root-mean-square Euclidean chord displacement. The resulting rooted W_2 matrix records the least pairwise semantic displacement; it does not observe the maintained information-to-exposure transmission map. The persisted artifact contains rooted W_2 distances, which the allocation objective above squares once at the certificate boundary. Section C documents the artifact construction and sample roster.

The variance evaluation, $\hat{\Sigma}_R$, uses the same 2018–2022 period as the article geometry after the news-only allocation is constructed. The exercise is therefore an in-sample descriptive ranking.

5.3 Allocation-anatomy design

The variance percentile answers whether the news-only allocation lands in an unusual part of the feasible variance distribution, but not what the rule selects or which transport separations support that decision. The allocation-anatomy design therefore reports the canonical firm weights, aggregates them by sector, and decomposes certificate credit into the additive unordered terms $q_i q_j W_{2,ij}^2$. These are interpretations of the constructed allocation rather than new return hypotheses.

5.4 Expanding-cutoff design

The cutoff diagnostic holds the frozen representation and optimization rule fixed while expanding the article window through each year-end from 2018 to 2022. For every cutoff, the analysis reports firm weights, effective N , the largest position, and one-way turnover from the preceding allocation. The terminal cutoff must reproduce the canonical allocation. Because the encoder is common across cutoffs and the entire accumulated corpus changes at each step, this sequence measures decision sensitivity to observed article coverage; it is neither a point-in-time trading backtest nor an event study.

5.5 Representation sensitivity design

The representation ladder studies sensitivity in the measurement of information geometry rather than introducing new economic hypotheses or selecting an encoder from the same return sample. Every arm holds fixed the priced firms, source article records, standardized-return covariance, reference laws, caps, and paired bootstrap schedule while changing one declared representation margin where possible. Model-specific input limits can still change the effective article text seen by an encoder.

The first margin is output width. Qwen3-Embedding-8B is evaluated at its full 4,096 coordinates and at 1,024, 256, and 64 coordinates. Its Matryoshka training is designed to keep leading-coordinate prefixes informative, so these arms probe compression within one frozen model rather than re-estimating coordinates from the return data. The second margin is model capacity. The 1,024-coordinate comparison between Qwen3-Embedding-8B and Qwen3-Embedding-4B holds width fixed, whereas their native 4,096- and 2,560-coordinate

comparison changes capacity and width jointly. Both Qwen models are obtained through OpenRouter.

The third margin is model family. At 1,024 coordinates, BAAI BGE-large-en-v1.5 changes model family, pretraining, and effective input length jointly relative to Qwen3-Embedding-8B, so the comparison is an external sensitivity rather than an identified architecture effect (Xiao et al., 2024). BGE-large-en-v1.5 is also obtained through OpenRouter.

The final margin is encoder vintage. The authors’ locally trained, 320-coordinate EttaX V0, V1, and V3 encoders hold architecture, optimization recipe, compute, tokenizer, and token budget fixed while varying only the Wikipedia training snapshot. V0 uses 20 December 2017, V1 uses 20 December 2020, and V3 uses 1 August 2026. Because V3 postdates both the article and return sample, it is a post-sample negative control rather than a valid point-in-time encoder. The EttaX encoders also differ materially in capacity from the production Qwen models, so the vintage contrasts remain descriptive sensitivities rather than identified vintage effects. Their benchmark-calibrated equivalence threshold is post-specified, making the equivalence assessment exploratory.

With the allocation, reference-population estimand, anatomy and cutoff diagnostics, return evaluation, and four measurement margins defined, the next section reports the resulting in-sample evidence.

6 Results

6.1 Main in-sample variance ranking

The main result uses the prespecified, 4,096-coordinate Qwen3-Embedding-8B representation. Across the four reference laws, its variance percentile ranges from 0.69% to 1.33%, compared with 21.1% to 28.6% for equal risk weights. The variance percentile is the share of feasible reference portfolios with variance no greater than the candidate’s. Lower is therefore better: a smaller percentile means that fewer reference portfolios attain equally low or lower variance. Table 1 reports this ranking under each prespecified reference law.

Table 1: In-sample variance percentile inside four prespecified feasible allocation populations. Entries are the share of 20 000 capped draws whose standardized variance is no greater than the candidate’s. Lower is better.

Reference population	Mean effective N	News-only	Equal risk
Uniform, 12.5% cap	27.00	0.72%	28.6%
Uniform, 15% cap	26.92	0.69%	28.4%
Effective- N matched, 15% cap	24.23	0.89%	25.4%
Concentrated, 15% cap	19.01	1.33%	21.1%

Under the two uniform laws, only 0.72% and 0.69% of draws have variance no greater than the news-only allocation’s. The corresponding shares are 0.89% under the effective- N matched law and 1.33% under the deliberately more concentrated law. Thus, a rule constructed without cross-asset return covariance lands near the first percentile of conventional variance across all four declared feasible populations.

The matched and concentrated populations make this ranking more informative than the two uniform comparisons alone. The matched law has mean effective N of 24.23, close to the candidate’s 23.65, yet only 0.89% of its draws attain equally low or lower variance. Even when mean effective N falls to 19.01, the share is only 1.33%. The low rank therefore survives comparisons that materially alter the concentration profile within the declared

feasible class; it is not solely a consequence of benchmarking the candidate against more diffuse portfolios.

Equal risk weights provide a familiar point of comparison within the same laws. Their percentiles are 28.6%, 28.4%, 25.4%, and 21.1%, respectively. These ranks remain well above the news-only ranks under every reference law. The comparison is a descriptive location within prespecified portfolio populations, not a hypothesis test or evidence of prospective performance.

6.2 Portfolio characteristics and conventional benchmarks

The percentile result says where the candidate lies within feasible reference populations but not how far it sits from familiar portfolio strategies. The equal-risk benchmark sets $q_i = 1/N$. Using the mapping $q_i(x) = x_i\sigma_i/A(x)$ gives

$$q_i = \frac{1}{N} \iff x_i^{\text{IV}} = \frac{\sigma_i^{-1}}{\sum_j \sigma_j^{-1}}.$$

It is therefore the inverse-volatility capital portfolio expressed in the normalized risk-weight coordinates of the empirical exercise, not an arbitrary second equal-weight portfolio. The sample GMV provides the opposite benchmark: it uses the complete in-sample covariance matrix that the news-only construction excludes. Table 2 provides that calibration using the same standardized return panel.

Table 2: In-sample descriptive portfolio benchmarks. Standardized variance is computed on the complete 2018–2022 aligned return panel; relative variance indexes the long-only sample GMV to 100. Returns evaluate the news-only allocation after construction but do not determine its weights.

Portfolio	Standardized variance	Rel. to GMV	Max. weight	Effective N
News-only	0.357	135.6	12.1%	23.65
Equal risk weights	0.390	147.8	–	–
Sample GMV	0.264	100.0	–	–

The news-only standardized variance is 8.3% lower than the variance of the equal-risk benchmark. It nevertheless remains 35.6% above the ex post long-only sample GMV. The empirical claim is therefore not that information geometry solves the conventional GMV problem without a covariance matrix. Rather, the news-only allocation lands unusually low in the variance distribution generated by the declared feasible laws while remaining short of the covariance-informed in-sample optimum.

The concentration diagnostics describe the decision object behind that rank. Its largest holding is 12.1%, and its effective number of names is 23.65. The candidate therefore differs from equal risk weighting and is not reduced to a one-name solution. Together with the matched-population result, these diagnostics show that the low rank is not mechanically explained by an extreme scalar concentration profile. They do not establish stability of the individual holdings or performance outside this sample.

6.3 Anatomy of the news-only allocation

The scalar concentration diagnostics do not reveal which firms the rule selects or which parts of the information geometry create its certificate. Figure 2 opens that decision object at three levels: firm weights, additive firm-pair credits, and sector weights.

The pair layer is the informative attribution level for this optimum. To see why, let $M = (W_{2,ij}^2)_{i,j}$ and write the zero-slack objective as $\mathcal{C}(q) = \frac{1}{2}q^\top Mq$. For every firm in the positive support of this solution, whose unit cap is nonbinding, the simplex first-order condition gives $(Mq^*)_i = \lambda$. Multiplying by q_i^* and summing over the support yields $\lambda = q^{*\top} Mq^*$. Consequently, the natural firm-level share proposed by the quadratic decomposition satisfies

$$\frac{q_i^*(Mq^*)_i}{q^{*\top} Mq^*} = q_i^* \quad \text{whenever } q_i^* > 0. \quad (24)$$

Firm certificate shares therefore reproduce the portfolio weights rather than provide a second diagnostic. The unordered pair terms remain informative:

$$c_{ij} := q_i^* q_j^* W_{2,ij}^2, \quad \mathcal{C}(q^*) = \sum_{i < j} c_{ij}. \quad (25)$$

They identify which weighted separations the optimizer actually uses.

Figure 2: Anatomy of the canonical news-only allocation. Panel (a) orders firms by sector and then by weight; horizontal lines mark the equal risk weight and the 12.5% cap used by the tightest reference population. Panel (b) reports the twelve largest unordered terms c_{ij} in (25) as shares of total certificate credit and distinguishes within- from cross-sector pairs. Panel (c) compares sector weights with the sector shares induced by equal risk weights. All panels describe the full-sample news-only allocation; they do not use returns or assign a causal role to sector membership.

The solution assigns positive weight to 38 of the 52 firms, so the effective- N statistic reflects a portfolio with many small positions and a limited set of larger ones rather than diffuse weight on every name. Table 3 makes the largest positions tangible. For each row, the strongest partner is the holding that produces its largest pair term in (25). A large position need not have the largest pair credit: the latter also depends on the counterpart's weight and their squared transport separation.

Ticker	Firm	Sector	Weight (%)	Partner	Pair credit (%)
AZN	AstraZeneca PLC	Healthcare	12.11	GOOG	1.51
GOOG	Alphabet Inc.	Communication Services	5.29	AZN	1.51
NFLX	Netflix Inc.	Communication Services	4.96	AZN	1.40
UAL	United Airlines Holdings Inc.	Industrials	4.80	AZN	1.28
ORLY	O'Reilly Automotive Inc.	Consumer Cyclical	4.19	AZN	1.22
TMUS	T-Mobile US Inc.	Communication Services	4.11	AZN	1.16
AAL	American Airlines Group Inc.	Industrials	3.95	AZN	1.04
SIRI	Sirius XM Holdings Inc.	Communication Services	3.82	AZN	1.10

Table 3: Largest positions in the canonical news-only allocation. Partner identifies the holding that forms the largest unordered additive certificate term with the row firm; pair credit reports that term as a percentage of total certificate credit.

The sector panels supply a diagnostic rather than an explanation. The news-only sector weights differ visibly from the sector shares implied by equal risk weights. Across the additive pair terms, 87.1% of certificate credit is cross-sector and 12.9% is within-sector. Thus the reported certificate is not generated by within-sector separation alone. The split does not establish that transport geometry contains information beyond sector labels: sector sizes, portfolio weights, and the number of available cross-sector pairs also affect it. It locates the certificate credit while leaving the economic source of those separations open.

6.4 Evolution across expanding information cutoffs

The canonical allocation pools articles through 2022. To examine whether that decision is peculiar to the terminal corpus, the same zero-slack problem is re-solved after expanding the article window through each year-end from 2018 to 2022. Figure 3 shows the resulting sequence. These are expanding information cutoffs, not separate calendar-year article samples.

(b) Allocation diagnostics by cutoff

	2018	2019	2020	2021	2022
Effective names	22.95	24.54	24.56	23.79	23.65
Largest weight (%; ticker)	9.3 TMUS	9.0 TMUS	8.3 TMUS	10.6 AZN	12.1 AZN
Turnover (%)	–	26.8	14.5	13.2	13.3

Figure 3: Evolution of the news-only allocation under expanding article cutoffs. Panel (a) reports firm weights for article windows ending in 2018, 2019, 2020, 2021, and 2022, with firms grouped by sector. Panel (b) reports the effective number of names, the largest weight and its ticker, and one-way turnover $\frac{1}{2}\|q_t - q_{t-1}\|_1$. The common frozen encoder is held fixed, and the terminal 2022 column reproduces the canonical allocation. The sequence measures decision sensitivity to accumulated articles; it is neither a prospective return test nor an event-study design.

The portfolio changes as the information set grows without becoming either one-name concentrated or equal-risk weighted. Across the five cutoffs, effective N remains between 22.95 and 24.56, while the largest weight ranges from 8.3% to 12.1%. One-way turnover ranges from 13.2% to 26.8%. The largest reallocation occurs when the first one-year corpus is extended through 2019: 26.8%, compared with 14.5% from 2019 to 2020. The sequence therefore does not display a uniquely large break at the 2020 cutoff. It cannot isolate a COVID effect in any case, because the design changes the entire accumulated article distribution at once and holds a common encoder fixed across cutoffs.

6.5 Representation sensitivity

The expanding-cutoff sequence changes the information set while holding the representation fixed. The final empirical question changes the representation itself. Table 4 shows the four measurement margins; Section D.1 reports the full ladder and paired bootstrap contrasts.

Table 4: Selected representation sensitivity of the news-only allocation. The percentile column reports the percentage of allocations under the effective- N reference law, calibrated to the primary Qwen3-Embedding-8B allocation, whose standardized variance is no greater than the candidate’s. Relative variance indexes the long-only sample GMV to 100. Lower is better in both columns. The complete ladder and paired bootstrap contrasts appear in Section D.1.

Encoder	Dim.	Canonical- N_{eff} percentile	Rel. GMV
Qwen3-8B full (primary)	4096	0.89	135.6
Qwen3-8B@1024	1024	0.82	135.3
Qwen3-4B@1024	1024	2.39	138.2
BGE-large-v1.5 full	1024	0.80	135.3
Qwen3-8B@64	64	0.02	128.4
EttaX V0	320	5.44	140.8
EttaX V1	320	7.27	142.0
EttaX V3	320	2.48	138.3

Moderate within-model compression leaves the outcome nearly unchanged: Qwen3-8B at 1,024 coordinates is close to the full-width primary representation in both reported metrics, and their paired interval includes zero. At the same fixed width, Qwen3-4B ranks higher in conventional variance than Qwen3-8B, and that paired difference survives Holm adjustment. BGE-large at 1,024 coordinates is again close to Qwen3-8B, so the sample does not support a simple model-family ordering.

The width ladder is non-monotone. The 64-coordinate Qwen3-8B stress cell has the lowest conventional-variance rank in the ladder, and its contrast with the 256-coordinate cell survives Holm adjustment. That outcome does not make 64 coordinates the preferred specification: the full-width 8B representation was prespecified, and every arm is evaluated on the same return sample. Instead, it shows that extreme compression can materially alter the geometry and selected allocation, in this case in a direction that improves the in-sample variance benchmark.

The matched EttaX vintages supply a separate sensitivity. Their outcomes vary across the three training snapshots; the V3–V1 contrast survives Holm adjustment, and none of the pairwise intervals satisfies the post-specified equivalence criterion. Because V3 postdates the sample and the equivalence threshold is exploratory, these comparisons neither identify a causal vintage effect nor establish representation invariance. Taken together, the ladder does not support a monotone “larger model is better” account. It shows instead that the primary result is empirically strong within the declared benchmark but remains sensitive to the measurement layer that creates the information geometry.

These comparisons are descriptive and in-sample: the same 2018–2022 return panel evaluates the news-only allocations after their construction. They describe how the rule ranks against the declared reference populations, not how it will perform prospectively. Section 7 interprets what these results establish within the maintained framework and where their boundaries lie.

7 Discussion and Limitations

Within its maintained transmission model and prespecified information geometry, the paper establishes a bounded positive implication. The certificate maps observed Wasserstein separation into a one-sided restriction on portfolio variance, and the zero-slack allocation rule minimizes the resulting certified upper bound without estimating cross-asset return covariance. In the 52-firm panel, that allocation falls near the first percentile of conventional

variance across four prespecified reference populations, while equal risk weights rank materially higher under every comparison. The evidence is therefore an unusually low location among feasible allocations, not covariance-free replication of the covariance-informed optimum. Five boundaries qualify what this finding establishes and what it does not.

The first is identification. The certificate is conditional on an antilipschitz carrier, firm-specific slack, one coherent joint exposure law, and the return bridge. Together, these maintained restrictions transmit observed information separation into a statement about portfolio risk, but the text data do not identify that transmission mechanism. The cost is interpretive: the certificate is valid under the declared restrictions rather than an unconditional implication of text geometry. At the zero-slack boundary, however, the carrier constant drops out of the normalized allocation through Corollary 1, so the selected risk weights depend only on the observed W_2 distances. The maintained restrictions therefore determine what the low variance ranking means economically—whether it reflects genuine risk reduction through information separation—rather than whether the allocation exists or whether its realized variance is low relative to the declared reference populations. Isolating the transmission would require identified or calibrated counterparts to the carrier, firm-specific slack, and return bridge.

The second boundary is representation dependence. The article selection, embedding model, and output width determine the measured distributions and may therefore alter the distances and portfolio weights. The representation ladder evaluates this sensitivity while holding the priced firms and return evaluation fixed, but it does not make the canonical Qwen3-Embedding-8B geometry invariant to measurement choices. Two features of the ladder sharpen the interpretive consequence. The width ladder is non-monotone: extreme compression to 64 coordinates materially alters the allocation, in this case improving the in-sample variance ranking, so the geometry is not simply degraded by truncation. The matched EttaX vintage contrasts do not satisfy the post-specified equivalence criterion, so the evidence does not support representation invariance even within a fixed architecture. The primary representation was prespecified, and the ladder evaluates sensitivity rather than selecting a winner from the same return data. Prespecified alternatives using different ground metrics, unbalanced clouds, or held-out evaluation windows would show which features of the geometry survive those measurement choices.

The third boundary concerns comparison-set design. The percentile ranking is relative to four prespecified Dirichlet-capped reference populations, and the choice of concentration parameter and cap determines what “low” means. The matched population addresses the most immediate confound: it calibrates mean effective N to the candidate’s, so the ranking does not arise solely from comparing a concentrated portfolio against diffuse ones. The deliberately concentrated population goes further, and the ranking survives. These four laws nevertheless remain maintained design choices. Alternative reference populations—market-capitalization-weighted draws, factor-tilted draws, or draws from the empirical distribution of a historical allocation universe—could rank the candidate differently. The evidence is that the allocation is unusually low under every declared comparison, not under every conceivable one.

The fourth boundary is portfolio implementation. The empirical exercise implements the standardized-asset specialization, in which unit marginal scales make capital weights coincide with normalized risk weights. The general raw-capital objective in (21) retains the marginal volatility scales through $A(x)^2$ and the risk-weight mapping $q(x)$. Constructing a capital-weight allocation from the certificate therefore requires the same marginal-scale inputs as an inverse-volatility portfolio, though it does not require cross-asset return

covariance. The standardized exercise isolates the certificate’s information channel cleanly, but the practical gap between the standardized and capital-weight allocations remains unquantified.

The fifth boundary is external validity. The empirical universe is a coverage-screened survivor panel of 52 firms with complete return histories, not a historical index-membership universe. The resulting evidence characterizes firms with the required source coverage rather than every investable firm or a changing historical universe. The information geometry and the return evaluation also draw on the same 2018–2022 period. The reported percentile is therefore descriptive: it is neither a point-in-time test nor an ex-ante guarantee of future realized variance. The expanding-cutoff sequence shows how the allocation evolves with accumulated articles, but it does not constitute out-of-sample evidence because the return evaluation period is unchanged. A prospective performance claim requires a frozen point-in-time construction in which the encoder, article corpus, and W_2 geometry are all fixed before the evaluation returns are observed, together with genuinely out-of-sample return evaluation. The present evidence demonstrates the framework’s implications for a specific panel and representation; whether those implications survive prospective evaluation is the immediate empirical priority. The conclusion returns to the conditional portfolio-risk certificate and its allocation rule within these boundaries.

8 Conclusion

Mean–variance portfolio choice conventionally begins by estimating a return covariance matrix, precisely the object that short and high-dimensional panels make difficult to estimate reliably. This paper takes a different route. It asks what observed differences between firms’ information distributions can certify about portfolio risk before cross-asset covariance is estimated. The resulting information certificate is a one-sided restriction on admissible portfolio variance, not a point estimate of the covariance matrix.

Related work establishes neighbouring implications of the same distributional geometry at other levels of aggregation. At the pairwise level, Gawronsky and Huang (2026a) derive a covariance envelope from Wasserstein separation. At the cross-sectional level, Gawronsky and Huang (2026b) form a barycentric interaction field through target-anchored Wasserstein barycentric reconstruction. The distinct step here is portfolio aggregation. An antilipschitz carrier with bounded firm-specific slack transfers observed W_2 separation into lower bounds on latent exposure separation; one coherent joint exposure law then aggregates those restrictions into a portfolio-risk bound. A maintained return bridge translates the exposure result into standardized and raw-return variance statements. The text determines the observed geometry, but it does not identify any of these transmission restrictions.

Within this bridge, multi-firm transport dispersion supplies the sharp certificate, while the weighted pairwise certificate provides the computationally simpler decision rule used in the empirical analysis. The investor minimizes the certified upper bound rather than an estimated portfolio variance. When firm-specific slack is zero, the common carrier scale changes how much variance is certified away but not the selected normalized risk allocation, which depends only on the observed W_2 geometry. Capital implementation still requires marginal volatility scales, but expected returns and cross-asset return covariance do not enter the allocation’s construction.

In the 52-firm 2018–2022 panel, the Qwen3-Embedding-8B news-only allocation falls between the 0.69% and 1.33% variance percentiles across four prespecified capped reference populations, while equal risk weights rank higher under each corresponding comparison. Its standardized variance is 8.3% below the variance of the equal-risk benchmark but

35.6% above the ex post long-only sample GMV. The evidence is therefore an unusually low location among ordinary feasible allocations, not covariance-free replication of the covariance-informed optimum. Portfolio anatomy further shows that 87.1% of the additive certificate credit comes from cross-sector pairs. This attribution locates the geometry used by the allocation; it does not identify a sector mechanism. Both the information geometry and the covariance used for evaluation draw on the same 2018–2022 period. The resulting ranking is therefore descriptive and in-sample: it illustrates the allocation implied by the maintained framework rather than identifying the information-to-risk transmission or predicting future portfolio variance.

As a theoretical restriction, the certificate can complement conventional covariance estimation with information about admissible portfolio risk that originates outside joint returns. The present paper does not incorporate the certificate into a shrinkage or constrained covariance estimator, nor does it establish the properties of such an estimator. Doing so is a natural extension when return histories are short or unstable.

More broadly, the construction is not intrinsically tied to corporate news or equities. Where economically relevant objects admit distribution-valued representations and a defensible transmission restriction links their observed geometry to latent risk, the same logic can generate one-sided restrictions on aggregate risk. The immediate empirical priorities are point-in-time construction, genuinely out-of-sample evaluation, and identified or calibrated counterparts to the maintained carrier, firm-specific slack, and return bridge. Those extensions would test the certificate’s practical value; the present contribution is the coherent portfolio-level object and the explicit bridge on which it depends.

A Formal verification

The main text contains the human-readable proofs of the barycentre representation, the aggregate transfer inequality, the information-certified cap, the sharp certificate, envelope exactness, certificate convexity, and the pairwise bridge. Where the bound is sharp, attainment of the optimal multi-marginal plan is supplied as a premise; the Lean record does not formalize the general existence theorem.

The formal record checks the displayed identities and bounds under their stated assumptions. These results concern the algebraic structure of the coherent portfolio certificate and do not validate the article-embedding proxy, the economic content of the carrier-and-slack restrictions, the empirical distance estimator, or the chronological evaluation design.

The exact machine-checked scope and assumptions are:

- Proposition 3: Machine-checked in the pinned Lean 4 / mathlib v4.31.0 workspace without assuming that either the barycentre infimum or the multimarginal infimum is attained.
- Theorem 2: Machine-checked in the pinned Lean 4 / mathlib v4.31.0 workspace with heterogeneous weighted root-mean-square transmission slack and truncation at zero. The proof uses the unconditional barycentre–multimarginal equivalence and assumes no optimal barycentre or joint plan.
- Theorem 1: Machine-checked in the pinned Lean 4 / mathlib v4.31.0 workspace by composing the carrier-and-slack W2 floor with the coherent joint-law portfolio-variance cap. The theorem is conditional on the displayed transmission, slack, joint-law, and integrability hypotheses; it neither calibrates those inputs nor establishes a realized total-return or ex-ante empirical bound.
- Equation (18): Machine-checked as an additive portfolio-level sensitivity wrapper: if systematic standardized variance is at most one minus the certificate credit and the aggregate residual contribution is at most delta, total standardized variance is at most one minus the credit plus delta. Delta is an assumed budget, not an estimated structural parameter, and the theorem does not derive residual orthogonality.
- Theorem 4: Machine-checked by continuity and compactness in the pinned Lean 4 / mathlib v4.31.0 workspace. The result establishes existence and the inherited risk guarantee, not uniqueness, unconditional convexity for an arbitrary distance matrix, or superior realized variance relative to competing portfolios.
- Theorem 3: Machine-checked in the pinned Lean 4 / mathlib v4.31.0 workspace by composing the aggregate carrier floor with an attainment-free multi-marginal variance envelope; no optimal joint plan or barycentre is assumed to exist. It is sharper than the pairwise certificate in two independent respects, subtracting one weighted root-mean-square slack radius in aggregate rather than two radii per pair,

and dominating any weighted sum of pairwise floors. It remains conditional on the displayed carrier, slack, joint-law, and integrability premises and calibrates none of them.

- Proposition 2: Machine-checked in the pinned Lean 4 / mathlib v4.31.0 workspace as an exact greatest-element statement, so the multi-marginal bound is not merely valid but unimprovable within the coherent-joint-law class. Attainment is a supplied premise: no general existence theorem for an optimal multi-marginal plan is claimed, and the result says nothing about which joint law the data realize.
- Theorem 5: Machine-checked in the pinned Lean 4 / mathlib v4.31.0 workspace. Convexity is conditional on the stated curvature property of the squared distance matrix and is asserted for no other matrix; whether a given empirical matrix satisfies it is a separate numerical question the theorem does not answer. Convexity concerns the standardized objective along weight mixtures and implies neither uniqueness of a minimizer nor any claim about realized variance.
- Proposition 1: Machine-checked as an exact equality in the pinned Lean 4 / mathlib v4.31.0 workspace. It identifies the pairwise covariance-envelope correction as the two-asset case of the multi-firm construction, establishing that the two papers describe one object rather than two compatible ones. It imports no assumption or empirical result from the pairwise paper.

B Barycentre representation of dispersion

Proposition 3 (Barycentre representation). *For laws $P_1, \dots, P_n$ on $\mathcal{H}$ with finite second moments, (11) holds.*

For weights q on the simplex, set $\bar{x}_q := \sum_i q_i x_i$. The pointwise weighted-variance identity

$$\sum_{i < j} q_i q_j \|x_i - x_j\|^2 = \sum_i q_i \|x_i - \bar{x}_q\|^2$$

is the bridge between the two representations. Given any multimarginal coupling of $P_1, \dots, P_n$, the random barycentre $\bar{X}_q = \sum_i q_i X_i$ induces a law Q . Applying the identity and then minimizing over multimarginal couplings gives the direction from the joint-coupling infimum to the barycentre infimum.

Conversely, take couplings of (P_i, Q) whose costs approach $W_2^2(P_i, Q)$ and glue their conditional laws given the common Q -distributed variable. The resulting multimarginal coupling has the required marginals. Conditionally on that common variable, the pointwise weighted-variance minimum gives

$$\sum_{i < j} q_i q_j \|X_i - X_j\|^2 \leq \sum_i q_i \|X_i - Q\|^2.$$

Taking expectations, then infima over the couplings and over Q , gives the reverse inequality. Thus the infimum values agree without assuming that either infimum is attained.

C Data and W2 artifact construction

The empirical universe begins from 53 firms with article embeddings. Return alignment leaves 52 firms and 1207 common daily observations; WBA is the only embedding-covered

name without a return series. Each article carries a creation date, URL hash, firm identifier, and a 4,096-dimensional Qwen3-Embedding-8B embedding. The representation normalizes every row to unit Euclidean norm, and the ground cost is Euclidean chord distance.

The registry distinguishes transport order from ground-cost exponent. The W_2 entries use balanced quadratic transport, rooted normalization, and ground exponent one. The persisted artifact is rooted W_2 ; Paper 3 squares it once at the certificate boundary, with regression tests enforcing that transition.

Balanced assignment currently requires equal empirical cloud sizes. Rows are first restricted by article date and then ordered by URL hash. The common sample sizes are 6, 19, 32, 64, and 128 at the respective 2018 through 2022 annual cutoffs. This rule retains all 52 priced firms rather than deleting firms with thin coverage.

The canonical priced W_2 roster used by the certificate and its diagnostics is listed in Table 5.

Table 5: Canonical empirical roster: ticker symbol, firm name, and sector label from Nasdaq summary metadata for the firms in the canonical priced W_2 geometry, sorted by sector then symbol. Authors’ calculations.

D Supplementary empirical results

The main text reports the conventional benchmark values in Table 2. Figure 4 provides the corresponding visual comparison.

Figure 4: Standardized in-sample variance relative to the full-sample long-only GMV benchmark. The news-only allocation is a descriptive zero-slack maximizer of the news certificate.

D.1 Complete embedding-representation sensitivity

The sensitivity tables hold the priced firms, standardized-return covariance, reference laws, caps, and bootstrap scheme fixed while changing the representation. For representation r , let $I_r = 100 V(q_r)/V(q_{\text{GMV}})$ denote its relative-GMV index. Each paired estimand is $\Delta_{c,r} = I_c - I_r$ in index points, so a negative contrast favours the candidate allocation on conventional variance. The common return bootstrap re-standardizes returns and recomputes the GMV denominator in each draw. Consequently, a dash means that the news-only allocation violates the fixed law’s cap; the cap is not relaxed to manufacture a percentile.

Encoder	Dim.	Uniform 12.5%	Uniform 15%	Canonical- N_{eff}	Concentrated 15%	Rel. GMV
Qwen3-8B full (primary)	4096	0.72	0.69	0.89	1.33	135.6
Qwen3-4B full	2560	1.23	1.23	1.36	1.92	136.7
Qwen3-8B@1024	1024	0.66	0.60	0.82	1.26	135.3
Qwen3-4B@1024	1024	2.20	2.28	2.39	2.85	138.2
BGE-large-v1.5 full	1024	–	0.59	0.80	1.23	135.3
Qwen3-8B@256	256	0.97	0.97	1.10	1.62	136.2
Qwen3-8B@64	64	0.01	0.02	0.02	0.06	128.4
EttaX V0	320	–	5.24	5.44	5.37	140.8
EttaX V1	320	7.48	7.32	7.27	7.25	142.0
EttaX V3	320	–	2.37	2.48	2.94	138.3
Equal risk weights	–	28.63	28.42	25.40	21.06	147.8

Table 6: Representation sensitivity of the news-only allocation across seven base representations and three matched EttaX encoder vintages on the common 52-firm, 1,207-date standardized-return panel. The four middle columns report the percentage of fixed-law allocations with standardized variance no greater than the candidate’s; lower is better. Relative variance indexes the long-only sample GMV to 100, so values above 100 measure percentage excess variance and lower is better. A dash marks a candidate that violates the law’s unchanged cap. The effective- N law is calibrated to the primary Qwen3-Embedding-8B allocation. Returns evaluate every fixed news-only allocation in sample; they do not construct it.

Contrast ($c - r$)	Estimate	95% CI	Raw p	Holm p	Bound	Equiv.

Table 7: Paired stationary-return-bootstrap contrasts for the ten-cell representation ladder. The seven base contrasts are descriptive candidate-minus-reference relative-GMV index-point differences, so a negative estimate favours the candidate. Raw p -values are two-sided add-one sign-tail probabilities; Holm adjustment is applied separately to the seven base and three vintage contrasts. The EttaX rows additionally use the BGE-large-minus-Qwen3-8B@1024 interval as a benchmark-calibrated, post-specified robustness threshold. Equivalence requires strict containment of the full interval; this is not a causal or architecture-only comparison.

The full-width-to-1,024 Qwen3-8B contrast includes zero, so moderate truncation does not reject zero difference in relative variance. At fixed 1,024 width, the Qwen3-4B comparison and the 64-coordinate Qwen3-8B stress cell differ after Holm adjustment. None of the EttaX vintage intervals satisfies the stated equivalence bound.
