August 2026

Abstract

Option prices are prices of insurance, so the risk-neutral probabilities they imply overstate physical crash risk. A power utility pricing kernel undoes the premium. But finitely many contracts trade, each at a bid and an ask, and many distributions fit inside the spreads. Each implies its own crash probability and expected loss below a crash threshold. This paper characterizes the attainable pairs exactly. With bounded support, they form a compact convex set. We call its boundary the physical crash frontier. It separates what the quotes admit from what they rule out. Both coordinates are ratios of moments, yet finite second-order cone programs trace the frontier. In a thousand weekly S&P 500 cross sections, quotes beyond the two puts nearest the threshold shrink the admissible probability range by a median of about 80 percent. Remove the bound, and a vanishing mass deep in the right tail inflates the denominator of those ratios, so the crash probability slides toward zero while every quote stays priced within its spread. The collapse occurs precisely when risk aversion exceeds that of the log investor. A positive floor requires a tail restriction the quotes cannot supply. What the quotes supply is the physical crash frontier.

Keywords: physical crash frontier, physical crash probability, partial identification, bid and ask quotes, pricing kernel

JEL Classification: G12, G13, C14, C61

1 Introduction

Severe market declines are difficult to measure for the same reason they matter: they are rare. At horizons of a few weeks, realized returns carry little information about the probability of a crash or the depth of losses once a threshold is crossed. Option markets price this risk continuously, and puts struck below the threshold trade at observable bid and ask quotes. But option prices are state prices. They measure the value of protection, and the same fear that makes measurement urgent also raises that value: risk-neutral crash probabilities overstate physical crash risk, most severely in times of stress (Martin and Shi, 2026). Converting prices into physical probabilities requires a restriction on some investor's preferences. The question this paper answers is how much the contracts that actually trade reveal about physical crash risk once that restriction is imposed.

The standard empirical route fits a smooth surface through the observed strikes and reads a single risk-neutral density from its curvature. The fitted surface mixes market information with assumptions about payoffs that never traded, and it hides how much the quote cross section itself constrains the answer. We keep the ambiguity explicit. For a fixed cross section, we collect every risk-neutral distribution that prices each retained quote within its spread, has unit forward mean, and is supported on a bounded interval. Zhuang (2026) characterizes the joint sets that the quote and forward restrictions alone generate

for the risk-neutral probability and depth of a crash. Those sets discipline the prices of crash insurance, and a price of insurance blends the probability of the loss with the compensation for bearing it.

This paper takes the remaining step. Each admissible distribution is mapped through the pricing kernel of a power utility investor who holds the market, the restriction of [Martin \(2017\)](#) as generalized by [Martin and Shi \(2026\)](#), whose crash probability bounds forecast realized crashes. The image is the physical distribution as that investor perceives it. Every statement below is conditional on that kernel: the results describe what the quotes imply for this investor.

Two coordinates summarize the physical crash risk each admissible distribution implies: the probability that the market finishes below the threshold, and the expected loss below it, which the paper calls the shortfall. Collecting these pairs across all admissible distributions yields an identified set in the sense of the partial identification literature ([Manski, 2003](#)). We call the boundary of that set the cross section's physical crash frontier. It separates the risk scenarios the quotes admit from those they rule out. The set is convex and compact, and its support function is the value of a finite second-order cone program. Under an explicit regularity condition the set is sharp: every point is generated, or approached arbitrarily closely, by an admissible distribution, and every excluded point is bounded away from all of them. The construction nests its risk-neutral predecessor as the $\gamma = 0$ member of a one-parameter family indexed by risk aversion. Under the maintained kernel and support condition, the frontier is what the quotes pin down. Everything tighter is an assumption.

The step from prices to physical probabilities changes the mathematics of the problem. Risk-neutral crash quantities are linear in the distribution, and their sets are computed by linear programming. Physical quantities are ratios. Under the $\gamma = 2$ benchmark, the conversion weights each state by the square of its normalized market payoff, so the crash probability becomes the second moment of the crash states divided by the second moment of all states. The denominator is the problem. It collects every state, including payoffs far above the last quoted strike, where no contract trades, so distributions that price every quote identically can still disagree about it. A vanishing sliver of mass, placed at an ever larger payoff, inflates it without limit, so the physical probability slides toward zero while every quote stays priced. This tail dilution channel is why no finite cross section of vanilla quotes, on its own, bounds the power utility investor's crash probability away from zero, and why a positive floor requires a restriction on the far right tail. The support condition is therefore a substantive assumption, and the analysis makes its cost explicit. Conditional depth, the expected further decline given a crash, is immune to the channel: it is the ratio of shortfall to probability, and their common denominator cancels.

Empirically, the traded quotes are informative, and their information is concentrated. The sample contains more than a thousand S&P 500 cross sections, sampled weekly from 2013 through 2023 at three fixed horizons around one month. Expanding the quote set from the two puts nearest a ten percent decline threshold to all retained out-of-the-money quotes shrinks the crash probability interval by a median of about 80 percent. Most of the contraction arrives with the six additional puts closest to the threshold. Even with every retained quote, the upper endpoint stays two to three times the lower endpoint. The resulting sets track market conditions, rising during the August 2015 selloff, early 2018, the COVID-19 crisis, and the 2022 selloff. Both endpoints jump upward together in March 2020: stress widens the range of crash probabilities the quotes admit at the same time as it raises their level.

The frontier is where the joint nature of identification pays off. Risk scenarios are stated in physical terms, a crash probability paired with an expected loss, so screening them requires the joint set of the physical quantities. Marginal intervals overstate what any single distribution can deliver, because their endpoints are generally attained by different distributions. The physical crash frontier cuts these unattainable corners away, and it cuts deepest in the shortfall direction. A candidate pair describes a feasible scenario only if one admissible distribution delivers both coordinates at once, and checking a pair is a single conic feasibility problem (Corollary 3.5).

The paper proceeds as follows. Section 2 places the analysis in the literature. Section 3 develops the identification framework and the exact computation. Section 4 describes the data and design. Sections 5 and 6 report the marginal and joint results, and Section 7 concludes. Appendices collect the proofs, the log-investor benchmark, and supplementary evidence.

2 Related Literature

With a continuum of option prices, the risk-neutral distribution is identified under regularity conditions (Breedon and Litzenberger, 1978). Empirical work builds on that identification: Pan (2002) estimates jump risk premia from the joint dynamics of spot and option prices in a parametric model, Backus et al. (2011) compare disaster distributions implied by index options with those calibrated to macroeconomic data, and Bollerslev and Todorov (2011) separate compensation for tail events from the events themselves, reading risk-neutral jump tails from short-maturity options and physical jump tails from high-frequency returns. The premium component of these tail measures forecasts returns (Bollerslev et al., 2015). Each approach reaches its point estimates by adding structure, whether a parametric model or a tail extrapolation. We start one step earlier and ask what is identified before that structure is imposed.

Physical crash probabilities can be approached from three directions. Survey respondents report subjective crash probabilities far above historical crash frequencies (Goetzmann et al., 2016), a direct window on beliefs. Reading the assessments embedded in traded prices takes a different route. Recovery arguments attempt to extract physical probabilities from state prices while replacing preference restrictions with structural ones: Hansen and Scheinkman (2009) develop the operator decomposition that underlies these arguments, Ross (2015) establishes recovery for a Markov state with a transition-independent kernel, and Borovička et al. (2016) show that the recovered measure differs from the physical one whenever the kernel has a nondegenerate martingale component, so an explicit restriction is unavoidable. A third route supplies the restriction directly. Ait-Sahalia and Lo (2000) and Jackwerth (2000) infer risk aversion by comparing option-implied state prices with return histories, Rosenberg and Engle (2002) estimate time-varying pricing kernels projected on market returns, and Bliss and Panigirtzoglou (2004) calibrate utility so that the transformed densities best forecast realized returns.

The restriction maintained here descends from Martin (2017), whose benchmark investor has log utility and holds the market. Martin and Shi (2026) generalize his expectation identity to arbitrary risk aversion, convert risk-neutral crash probabilities into physical ones, document that the risk-neutral versions cry wolf, overstating crash risk most severely in crises, and calibrate risk aversion to two on market returns. Their stock-level bounds rely on Fréchet–Hoeffding arguments because marginal option prices do not identify the joint distribution of a stock with the market. For the market index itself, the dependence problem disappears, and identification uncertainty comes instead from finite strikes, bid–ask intervals, and the unobserved right tail.

A finite cross section turns identification into a generalized moment problem, and the idea of answering with a set is old. Lo (1987) derives upper bounds for option prices and expected payoffs from moment restrictions, and Bassett (1997) bounds the probabilities of future prices by the set of distributions that could have generated the observed option values. Bertsimas and Popescu (2002) derive best-possible bounds on option prices from moment information by semidefinite programming, and King et al. (2005) compute arbitrage-free price bounds for a claim from the prices of traded options through convex duality. Davis and Hobson (2007) characterize when a finite set of option prices is consistent with an arbitrage-free model. Cox and Obłój (2011) derive model-free bounds for barrier claims from call and digital call quotes, where mass exactly at a barrier changes the answer. In a single-maturity bid–ask martingale transport problem, Liang et al. (2026) derive a square-root convergence rate for upper-semicontinuous payoffs of bounded variation as spreads vanish.

We read the resulting solution sets as identified sets in the sense of Manski (2003) and describe them through their support functions, following Beresteanu and Molinari (2008). The closest computational relatives are Barratt et al. (2024), who bound the cumulative distribution and distributional risk measures over risk-neutral probabilities on a discretized price grid, and van Eekelen (2023), who extends generalized moment duality to conditional expectations, the fractional form that conditional depth takes here. The direct predecessor is Zhuang (2026), which derives sharp joint bounds on risk-neutral crash probability and conditional depth from finite bid–ask quotes and shows that separate marginal extrema need not be jointly attainable.

We differ from this predecessor in the object that is identified: the bounds here concern physical crash

risk under the benchmark kernel. Positive risk aversion makes the transform to physical probabilities normalize by a moment of the unknown distribution. The normalization turns linear objectives into ratios, replaces the linear programs of the risk-neutral analysis with second-order cone programs, and demands a support condition that the risk-neutral problem does not need. That condition is the source of the tail identification problem studied below.

3 From Option Quotes to Sets of Physical Crash Probabilities

We work one cross section at a time. This section defines the admissible risk-neutral distributions, constructs the physical crash quantities they imply, and characterizes and computes the identified sets exactly.

3.1 Normalized prices and admissible measures

Fix a valuation date t and an option maturity T . Let D denote the discount factor and F the forward price of the cross section. The random variable S_T is the terminal index level, and we work with the forward-normalized terminal level

$$X = \frac{S_T}{F}. \quad (1)$$

The normalization makes X dimensionless, and under the normalized risk-neutral measure $\mathbb{Q}$ its first moment equals one.

Quote i has absolute strike K_i^{abs} and normalized strike $k_i = K_i^{\text{abs}}/F$. We write $\underline{c}_i$ and $\bar{c}_i$ for the normalized bid and ask of a call payoff at that strike, so a retained call quote imposes

$$\underline{c}_i \leq \mathbb{E}_{\mathbb{Q}}[(X - k_i)^+] \leq \bar{c}_i. \quad (2)$$

Put quotes enter the same form through put–call parity: their normalized endpoints are the put bid and ask divided by DF , with $1 - k_i$ added to each endpoint.

Let $\mathcal{I}$ denote a finite set of retained quote indices, and let $B > 1$ be an upper support bound. The admissible set is

$$\mathcal{M}(\mathcal{I}) = \left\{ \mathbb{Q} : \mathbb{Q} \text{ is a probability measure on } [0, B], \right. \\ \left. \mathbb{E}_{\mathbb{Q}}[X] = 1, \quad \underline{c}_i \leq \mathbb{E}_{\mathbb{Q}}[(X - k_i)^+] \leq \bar{c}_i \quad \text{for every } i \in \mathcal{I} \right\}. \quad (3)$$

In general $\mathbb{Q}$ is the normalized state-price measure for maturity T , and when discounting is deterministic it is the usual risk-neutral measure. Support on $[0, B]$ is a maintained economic restriction whose role Section 3.5 isolates. The set $\mathcal{M}(\mathcal{I})$ also depends on B and on (D, F) , which are held fixed throughout the analysis, so we suppress them and keep only the quote set $\mathcal{I}$, the object the empirical design varies.

3.2 The power utility investor and the crash quantities

Assumption 3.1 (Power utility pricing kernel). *The investor is marginal in the market, has CRRA utility with coefficient $\gamma > 0$, and is fully invested in market wealth. Her gross return on market wealth is $R_m = cX$ for a constant $c > 0$, her stochastic discount factor is proportional to $R_m^{-\gamma}$, and gross returns are strictly positive.*

For each $\gamma > 0$ and admissible $\mathbb{Q}$, let $M_{\gamma}(\mathbb{Q}) = \mathbb{E}_{\mathbb{Q}}[X^{\gamma}]$. Assumption 3.1 defines the physical measure $\mathbb{P}_{\gamma}^{\mathbb{Q}}$ perceived by the investor through

$$\frac{d\mathbb{P}_{\gamma}^{\mathbb{Q}}}{d\mathbb{Q}} = \frac{X^{\gamma}}{M_{\gamma}(\mathbb{Q})}. \quad (4)$$

Normalized state pricing makes $d\mathbb{Q}/d\mathbb{P}$ proportional to the stochastic discount factor. Since that factor is proportional to $X^{-\gamma}$, inversion and normalization under $\mathbb{Q}$ give the displayed density. The transform restates, for the normalized terminal level, the expectation identity that [Martin \(2017\)](#) derives for a fully invested log investor and [Martin and Shi \(2026\)](#) extend to arbitrary risk aversion. The support and forward restrictions imply $0 < M_\gamma(\mathbb{Q}) \leq B^\gamma$, so the transform is well defined for every admissible measure.¹

Fix a threshold $K \in (0, 1)$, held constant throughout, and define the crash event $\{X \leq K\}$. For each exponent $r \geq 0$, define the truncated moment

$$A_r(\mathbb{Q}) = \mathbb{E}_{\mathbb{Q}}[X^r \mathbf{1}\{X \leq K\}].$$

The crash probability and the unconditional shortfall, the expected loss below the threshold, are

$$q_{\gamma,K}(\mathbb{Q}) = \mathbb{P}_{\mathbb{Q}}^\gamma(X \leq K) = \frac{A_\gamma(\mathbb{Q})}{M_\gamma(\mathbb{Q})}, \quad (5)$$

$$\ell_{\gamma,K}(\mathbb{Q}) = \mathbb{E}_{\mathbb{P}_{\mathbb{Q}}^\gamma}[(K - X)^+] = \frac{KA_\gamma(\mathbb{Q}) - A_{\gamma+1}(\mathbb{Q})}{M_\gamma(\mathbb{Q})}. \quad (6)$$

When $A_\gamma(\mathbb{Q}) > 0$, conditional depth is the ratio

$$s_{\gamma,K}(\mathbb{Q}) = \mathbb{E}_{\mathbb{P}_{\mathbb{Q}}^\gamma}[K - X \mid X \leq K] = K - \frac{A_{\gamma+1}(\mathbb{Q})}{A_\gamma(\mathbb{Q})} = \frac{\ell_{\gamma,K}(\mathbb{Q})}{q_{\gamma,K}(\mathbb{Q})}. \quad (7)$$

Thus $\ell_{\gamma,K}$ measures the unconditional distance below K , while $1 - K + s_{\gamma,K}$ is the conditional decline from the normalized forward.² Setting $\gamma = 0$ in (5)–(6) makes the transform the identity and recovers the risk-neutral crash probability and normalized put value whose joint sets [Zhuang \(2026\)](#) characterizes. That paper places no upper bound on the state, so the $\gamma = 0$ sets here are the support-capped counterparts of its joint sets. Positive γ reweights each admissible measure by X^γ , undoing the premium that state prices attach to low-payoff states: probability mass shifts toward high-payoff states, physical crash probabilities fall below their risk-neutral counterparts, and, through $M_\gamma(\mathbb{Q})$, the reweighting is tied to a global moment of the unknown distribution.

Mass exactly at the threshold needs its own coordinate. Every retained payoff $(X - k_i)^+$ is continuous, so a finite quote cross section cannot separate an atom at K from mass just above it, yet the two differ for the closed event $\{X \leq K\}$. Let $a_K = \mathbb{Q}\{K\}$ and let $R_r(\mathbb{Q}) = \mathbb{E}_{\mathbb{Q}}[X^r \mathbf{1}\{X < K\}]$ denote the open truncated moment. Then

$$A_r = R_r + K^r a_K, \quad KA_\gamma - A_{\gamma+1} = KR_\gamma - R_{\gamma+1}, \quad (8)$$

so an atom at the threshold adds $K^\gamma a_K / M_\gamma(\mathbb{Q})$ to the crash probability and nothing to the shortfall.

3.3 The identified sets and their geometry

Each admissible measure delivers one probability–shortfall pair. The identified set collects every pair that admissible measures attain or approach:

$$\Theta_{q\ell}^\gamma(I) = \text{cl} \left\{ (q_{\gamma,K}(\mathbb{Q}), \ell_{\gamma,K}(\mathbb{Q})) : \mathbb{Q} \in \mathcal{M}(I) \right\}, \quad (9)$$

where cl denotes Euclidean closure. The closure matters because the event indicator jumps at K : a sequence of admissible measures can slide mass toward the threshold and change the event probability only in the limit, so the raw image need not be closed. Conversely, any point outside $\Theta_{q\ell}^\gamma(I)$ is at a positive distance from every pair an admissible measure can generate.

¹In Assumption 3.1, the relation $R_m = cX$ treats X as market wealth after deterministic dividend and numeraire adjustments. Admissible measures with mass at zero enter as a closure relaxation of the positive-return model and leave the closed identified sets unchanged (Lemma A.1).

²Throughout, shortfall refers to this expected loss below the fixed threshold, not to the quantile-based risk measure that shares the name.

Conditional depth is a ratio, and ratios need their own set:

$$\Theta_s^\gamma(I) = \text{cl} \left\{ K - \frac{A_{\gamma+1}(\mathbb{Q})}{A_\gamma(\mathbb{Q})} : \mathbb{Q} \in \mathcal{M}(I), A_\gamma(\mathbb{Q}) > 0 \right\}, \quad (10)$$

which is empty if no admissible measure gives the event positive weighted mass. Dividing the shortfall interval by the probability interval can overstate the range, because the measures that drive the four endpoints generally differ. The set in (10) keeps numerator and denominator tied to a common measure.

Theorem 3.2 (Identified sets under a power kernel). *Fix $\gamma > 0$ and $K \in (0, 1)$. Suppose $B < \infty$ and $\mathcal{M}(I)$ is nonempty. Then $\Theta_{q\ell}^\gamma(I)$ is a nonempty compact convex subset of*

$$\{(q, \ell) : 0 \leq q \leq 1, 0 \leq \ell \leq Kq\}.$$

If some admissible $\mathbb{Q}$ has $A_\gamma(\mathbb{Q}) > 0$, then $\Theta_s^\gamma(I)$ is a nonempty compact interval contained in $[0, K]$.

Convexity is not automatic, because mixing two measures does not mix their probability–shortfall pairs linearly: each pair carries its own normalizing denominator $M_\gamma(\mathbb{Q})$. The proof corrects for the denominators: mixing the measures themselves with weights inversely proportional to their normalizing moments delivers any prescribed convex combination of the two pairs, and admissibility survives because the quote and forward restrictions are linear in the measure. Appendix A records the algebra together with the compactness argument.

The boundary of the joint set records where the maintained restrictions bind, and we call it the cross section’s physical crash frontier. It is the physical counterpart of the risk-neutral crash frontier of Zhuang (2026). By Theorem 3.2 the set is compact and convex, so it is recovered from its support function (Rockafellar, 1970). For a compact convex $\Theta \subset \mathbb{R}^2$ and a direction $u = (u_q, u_\ell) \in \mathbb{R}^2$, write

$$H_\Theta(u) = \sup_{(q, \ell) \in \Theta} (u_q q + u_\ell \ell). \quad (11)$$

The value $H_\Theta(u)$ locates the supporting line with outward normal u , and the set is the intersection of the half planes those lines bound:

$$\Theta = \bigcap_{\|u\|_2=1} \{(q, \ell) : u_q q + u_\ell \ell \leq H_\Theta(u)\}.$$

The directions $(\pm 1, 0)$ and $(0, \pm 1)$ return the marginal interval endpoints, and intermediate directions carry the joint information that the marginals miss.

Adding quotes can only shrink the sets. If $I_1 \subseteq I_2$, then $\mathcal{M}(I_2) \subseteq \mathcal{M}(I_1)$, so both identified sets under I_2 are subsets of their counterparts under I_1 . This monotonicity organizes the empirical design in Section 4. The sets are monotone in the support bound as well: enlarging B enlarges the admissible set, so both identified sets expand weakly with B , and Section 5.4 traces this monotone family.

3.4 Exact computation under $\gamma = 2$

Theorem 3.2 holds for every $\gamma > 0$, and integer values of γ admit exact finite representations. The empirical benchmark is $\gamma = 2$, the calibrated choice in Martin and Shi (2026), and Appendix B develops the $\gamma = 1$ log investor.

From here on we fix $\gamma = 2$, drop the superscript on the sets, and write

$$q_{2,K}, \quad \ell_{2,K}, \quad s_{2,K}, \quad M(\mathbb{Q}) = \mathbb{E}_\mathbb{Q}[X^2], \quad \Theta_{q\ell}(I), \quad \Theta_s(I).$$

The exact statements below maintain one regularity condition.

Assumption 3.3 (Interior regularity (a Slater-type condition)). *Some $\mathbb{Q}^\circ \in \mathcal{M}(I)$ prices every retained quote strictly inside its interval, and there are bounded open intervals $U_- \subset (0, 1)$ and $U_+ \subset (1, B)$, disjoint from all strike and threshold boundaries, with $\mathbb{Q}^\circ(U_-) > 0$ and $\mathbb{Q}^\circ(U_+) > 0$.*

Computing a support value means maximizing a linear functional of $(q_{2,K}, \ell_{2,K})$ over all admissible measures. This is an infinite-dimensional problem whose objectives are ratios of moments. Two transformations turn it into a finite convex program: a change of scale removes the ratio, and a partition of the support at the strikes compresses the measure into finitely many moments whose feasible values are characterized exactly.

The change of scale is the linear-fractional normalization of [Charnes and Cooper \(1962\)](#). Define $\rho = M(\mathbb{Q})^{-1}$ and the scaled measure $d\tilde{\mathbb{Q}} = \rho d\mathbb{Q}$. The mass, forward, and second-moment restrictions become

$$\int d\tilde{\mathbb{Q}} = \rho, \quad \int X d\tilde{\mathbb{Q}} = \rho, \quad \int X^2 d\tilde{\mathbb{Q}} = 1, \quad (12)$$

and the two crash coordinates become linear in the scaled measure:

$$q_{2,K} = \int_{[0,K]} X^2 d\tilde{\mathbb{Q}}, \quad \ell_{2,K} = \int_{[0,K]} (K - X) X^2 d\tilde{\mathbb{Q}}. \quad (13)$$

Each quote band is multiplied by ρ , which keeps the quote restrictions linear in the pair $(\tilde{\mathbb{Q}}, \rho)$. Nothing is lost in the change of variables: since $0 \leq X \leq B$ and $\mathbb{E}_{\mathbb{Q}}[X] = 1$, the global moment satisfies $1 \leq M(\mathbb{Q}) \leq B$, so $\rho \in [1/B, 1]$ and $\mathbb{Q}$ is recovered from $(\tilde{\mathbb{Q}}, \rho)$ by division.

The partition uses the strikes themselves. Let $0 = b_0 < b_1 < \dots < b_J = B$ be the ordered distinct elements of $\{0, K, B\} \cup \{k_i : i \in \mathcal{I}, 0 < k_i < B\}$, and call the intervals $I_j = [b_j, b_{j+1}]$ cells. Decompose the scaled measure into local components,

$$\tilde{\mathbb{Q}} = \sum_j \mu_j,$$

where μ_j is a nonnegative measure supported on I_j . Such a decomposition always exists. An atom at a shared strike endpoint may be assigned to either adjacent cell, and no statement below depends on that choice, because every retained payoff is continuous there. The threshold is the one exception: any atom at K is assigned to the cell beginning at K and tracked by the explicit coordinate introduced below. For each cell j and integer order r , define the scaled cell moment

$$y_{r,j} = \int x^r d\mu_j(x),$$

and let the vector $\mathbf{y}$ collect these moments, with orders $r = 0, 1, 2, 3$ on the cells whose interiors lie below K and orders $r = 0, 1, 2$ elsewhere. These are all the moments the problem uses. The normalization (12) reads

$$\sum_j y_{0,j} = \rho, \quad \sum_j y_{1,j} = \rho, \quad \sum_j y_{2,j} = 1. \quad (14)$$

Every retained call payoff is affine on every cell, because its only kink sits at a strike and every strike is a cell boundary. The scaled value of quote i is therefore linear in the cell masses and first moments,

$$C_i(\mathbf{y}) = \sum_{j:b_j \geq k_i} (y_{1,j} - k_i y_{0,j}), \quad \rho \underline{c}_i \leq C_i(\mathbf{y}) \leq \rho \bar{c}_i, \quad (15)$$

and the targets (13) are linear in the second and third moments of the cells below the threshold.

The remaining question is which vectors $\mathbf{y}$ come from actual local measures. This is the truncated moment problem on an interval, and on bounded cells it has a complete answer. On a cell $[a, b]$ with orders up to three, a vector (y_0, y_1, y_2, y_3) is the moment sequence of some nonnegative measure on $[a, b]$ if and only if two localizing matrices are positive semidefinite:

$$\begin{pmatrix} y_1 - ay_0 & y_2 - ay_1 \\ y_2 - ay_1 & y_3 - ay_2 \end{pmatrix} \succeq 0, \quad \begin{pmatrix} by_0 - y_1 & by_1 - y_2 \\ by_1 - y_2 & by_2 - y_3 \end{pmatrix} \succeq 0. \quad (16)$$

On a cell with orders up to two, the conditions are the moment matrix

$$\begin{pmatrix} y_0 & y_1 \\ y_1 & y_2 \end{pmatrix} \succeq 0, \quad (17)$$

combined with the support inequalities

$$ay_0 \leq y_1 \leq by_0, \quad y_2 \leq (a+b)y_1 - aby_0. \quad (18)$$

These conditions are necessary and sufficient on a bounded interval (see Krein and Nudelman, 1977; Bertsimas and Popescu, 2002). A two-by-two positive semidefinite constraint is in turn one second-order cone constraint (Alizadeh and Goldfarb, 2003), since

$$\begin{pmatrix} u & v \\ v & w \end{pmatrix} \succeq 0 \iff u \geq 0, \quad w \geq 0, \quad \|(2v, u-w)\|_2 \leq u+w.$$

Cell by cell, the feasible moment vectors form an intersection of linear restrictions and second-order cone constraints.

One coordinate remains: the threshold atom of Section 3.2. Let $\tilde{a}_K \geq 0$ denote the scaled event mass at $X = K$. The atom is booked in the cell beginning at K , whose moment conditions apply net of the atom, a bookkeeping step recorded in Appendix A. With $\mathcal{J}_-$ collecting the cells whose interiors lie below K , so that the cell beginning at K is excluded, the targets are the linear functions

$$q_{2,K} = \sum_{j \in \mathcal{J}_-} y_{2j} + K^2 \tilde{a}_K, \quad \ell_{2,K} = \sum_{j \in \mathcal{J}_-} (Ky_{2j} - y_{3j}), \quad (19)$$

so the atom adds probability and no shortfall, exactly as in (8).

The program is now complete. Its decision variables are the cell moments $\mathbf{y}$, together with the two scalars ρ and $\tilde{a}_K$. Its constraints are of three kinds: the global equalities (14), the pair of scaled quote inequalities (15) for each retained quote, and one moment cone per cell, (16) on the cells below the threshold and (17)–(18) elsewhere, with the cell beginning at K taken net of the atom. Maximizing the linear objective $u_q q_{2,K} + u_\ell \ell_{2,K}$ from (19) is therefore a finite second-order cone program (SOCP) for each direction u .³

Corollary 3.4 (Exact computation under $\gamma = 2$). *Suppose Assumption 3.3 holds. Then $\Theta_{q\ell}(\mathcal{I})$ equals the image of the SOCP feasible region in $(\mathbf{y}, \rho, \tilde{a}_K)$ under the linear map (19), and every support value $H_{\Theta_{q\ell}}(u)$ is both the SOCP optimum and the supremum over admissible measures. If some admissible measure has $A_2(\mathbb{Q}) > 0$, analogous programs give the endpoints of the closed interval $\Theta_s(\mathcal{I})$.*

Appendix A proves the corollary in two directions. Every admissible measure produces a feasible vector, and every feasible vector is produced by an admissible measure or by a limit of admissible measures. Assumption 3.3 supplies the approximating sequences. Conditional depth needs a second normalization: its denominator is the truncated second moment, so scaling by $A_2(\mathbb{Q})^{-1}$ makes the depth objective linear, and the same cells and moment cones apply. Unlike ρ , the depth scaling has no upper bound, so the depth programs need not attain their optimal values, which under Assumption 3.3 still equal the endpoints of the closed depth interval.

Corollary 3.5 (Scenario feasibility). *Under Assumption 3.3, a pair (q°, ℓ°) lies in $\Theta_{q\ell}(\mathcal{I})$ if and only if the SOCP feasible region is nonempty once the two linear targets (19) are fixed at (q°, ℓ°) . Screening a candidate crash scenario is one conic feasibility problem.*

³For integer γ , the same construction applies with cell moments up to order $\gamma + 1$ below the threshold and order γ elsewhere. The truncated moment conditions become positive semidefinite constraints on larger moment and localizing matrices (Krein and Nudelman, 1977; Bertsimas and Popescu, 2002), so the support values are computed by semidefinite programming. Second-order cones suffice exactly when $\gamma \leq 2$, where every matrix is two by two.

The corollary follows directly from Corollary 3.4: the identified set equals the image of the feasible region under a linear map, so membership of a candidate pair is equivalent to feasibility with the image coordinates pinned.

Assembling the identified sets from the programs is then direct. Each direction u is one SOCP whose solution returns the support value $H_{\Theta_{q\ell}}(u)$ together with an optimal pair (q, ℓ) on the frontier. The four coordinate directions give the marginal probability and shortfall intervals, and the two depth programs give the depth interval. For the frontier itself, a finite grid of unit directions produces an inner and an outer polygon that sandwich the set: the convex hull of the optimal pairs is contained in $\Theta_{q\ell}(\mathcal{I})$, while the intersection of the supporting half planes $\{(q, \ell) : u_q q + u_\ell \ell \leq H_{\Theta_{q\ell}}(u)\}$ over the grid contains it. The gap between the polygons measures what the grid can still miss, so the grid is doubled until the gap falls below a preset tolerance, and the figures plot the outer polygon. Half planes computed for a coarser quote set remain valid under every finer set, so intersecting the accumulated half planes yields frontiers that are nested by construction.

3.5 What the right tail identifies

The support cap matters because it controls the denominator of the $\gamma = 2$ transform. Quotes can be dense near the crash threshold and still leave the far right tail weakly constrained, and the finite cap is what prevents a small amount of probability at a very large value of X from carrying an arbitrarily large second moment. Let $\mathcal{M}_\infty(\mathcal{I})$ denote the admissible measures of (3) with $[0, B]$ replaced by $[0, \infty)$ and with finite second moment.

Proposition 3.6 (Zero lower bound under a perturbable right tail). *Suppose $\mathcal{M}_\infty(\mathcal{I})$ contains a measure $\mathbb{Q}^\circ$ whose option values lie strictly inside every retained quote interval and which has positive mass on bounded open intervals $U_- \subset (0, 1)$ and $U_+ \subset (1, \infty)$. Then*

$$\sup_{\mathbb{Q} \in \mathcal{M}_\infty(\mathcal{I})} M(\mathbb{Q}) = \infty, \quad \inf_{\mathbb{Q} \in \mathcal{M}_\infty(\mathcal{I})} q_{2,K}(\mathbb{Q}) = \inf_{\mathbb{Q} \in \mathcal{M}_\infty(\mathcal{I})} \ell_{2,K}(\mathbb{Q}) = 0, \quad (20)$$

and the closure of the joint image $\{(q_{2,K}(\mathbb{Q}), \ell_{2,K}(\mathbb{Q})) : \mathbb{Q} \in \mathcal{M}_\infty(\mathcal{I})\}$ contains the origin.

The mechanism is a vanishing tail perturbation. A mass of order $H^{-3/2}$ placed at a state H far in the right tail changes fixed-strike option values by a vanishing amount but raises the second moment at order $H^{1/2}$. A small transfer between U_- and U_+ restores total mass and the forward restriction, and strict quote slack absorbs the remaining option-value changes. Since $A_2(\mathbb{Q}) \leq K^2$, the inflated denominator drives $q_{2,K}$ to zero, and it drives the unconditional shortfall to zero along the same sequence: without a support bound, the quotes cannot exclude physical distributions that assign the crash negligible probability and negligible expected loss. Conditional depth, the ratio of the two vanishing coordinates, is immune to this channel because $M(\mathbb{Q})$ cancels from its ratio, though its set can still respond to right-tail restrictions through the quote and forward constraints.

Remark 3.7 (Log utility is the dividing line). The collapse is not specific to $\gamma = 2$. For $\gamma \leq 1$, Jensen's inequality and the forward restriction give $M_\gamma(\mathbb{Q}) \leq 1$ for every admissible measure, so mass far in the right tail cannot inflate the denominator of the transform. For every $\gamma > 1$, with $\mathcal{M}_\infty(\mathcal{I})$ restricted to measures whose moment of order γ is finite, the construction in the proof applies with mass $H^{-(1+\gamma)/2}$ at the state H : option values change by $O(H^{(1-\gamma)/2})$, the moment M_γ grows without bound, and $q_{\gamma,K}$ and $\ell_{\gamma,K}$ vanish along the sequence. The dilution channel opens exactly when the investor is more risk averse than the log investor.

4 Data and Design

4.1 SPX option cross sections

The data are end-of-day bid and ask quotes on S&P 500 index options from OptionMetrics, covering January 2013 through August 2023. We retain quotes with positive strikes, nonnegative bids, positive

asks, uncrossed bid–ask intervals, and positive trading volume. Quotes enter the analysis only through these intervals. The sample uses exact calendar horizons of 23, 30, and 37 days and keeps at most one cross section per horizon in a calendar week, observed on Wednesdays. It contains 1,115 horizon-specific observations covering 537 distinct calendar weeks. Each cross section carries its own discount factor and forward.

4.2 Crash event and nested quote sets

The main event is a terminal decline of at least 10 percent from each cross section’s forward, so $K = 0.90$. Appendix C examines the more extreme event $K = 0.85$. The main support condition $B = 5$ allows the terminal index level to reach five times its forward over a 23–37 day horizon. It is a loose economic bound, and its only bite is to rule out states whose arbitrarily large market payoff dominates the kernel normalization. Section 5.4 examines tighter and looser caps and the unbounded specification.

The design expands the quote set in four steps. The first set, $\mathcal{I}^{\text{pair}}$, contains the closest retained put strike on each side of K . The second, $\mathcal{I}^{\text{local}}$, adds the six nearest additional put strikes, for eight in total. The third, $\mathcal{I}^{\text{wing}}$, contains the complete retained out-of-the-money (OTM) put wing. The final set, $\mathcal{I}^{\text{OTM}}$, adds all retained OTM calls and so comprises every retained OTM quote. Thus

$$\mathcal{I}^{\text{pair}} \subseteq \mathcal{I}^{\text{local}} \subseteq \mathcal{I}^{\text{wing}} \subseteq \mathcal{I}^{\text{OTM}}. \quad (21)$$

By the monotonicity of Section 3.3, every interval and every support value contracts weakly along this sequence, so the design separates information near the event threshold from information in the rest of the put wing and on the call side.

4.3 Reported statistics, verification, and inference

For each cross section we solve the programs of Section 3.4 and obtain the closed identified sets. All results condition on $\gamma = 2$, $K = 0.90$, $B = 5$, and each cross section’s fixed discounting and forward. Summaries are formed separately by horizon: the reported lower endpoint is the median of the lower endpoints across cross sections, and similarly for the upper endpoint. The main measure of information is the proportional reduction in the width of the crash probability interval. For nested quote sets $\mathcal{A} \subseteq \mathcal{B}$ with widths $w^{\mathcal{A}} > 0$ and $w^{\mathcal{B}}$, the reduction within a cross section is $\Delta_{\mathcal{A} \rightarrow \mathcal{B}} = 1 - w^{\mathcal{B}}/w^{\mathcal{A}}$, and we report its median across cross sections within each horizon. Sampling variation of these medians is assessed with a circular block bootstrap on calendar weeks, using eight-week blocks and 2,000 replications stratified by horizon (Politis and Romano, 1992; Sharipov and Wendler, 2013). Bracketed entries are percentile 95 percent intervals.

Assumption 3.3 is verifiable one cross section at a time. For each cross section we construct an admissible measure that prices every retained quote strictly inside its interval and places mass on both sides of the forward away from the strike and threshold boundaries. The construction succeeds in 1,111 of the 1,115 cross sections, and Table 4 in Appendix C reports the counts by horizon.

The all-OTM programs are solved to verified optimality in 1,098 cross sections, and these form the samples of Table 1. Cross sections in which a program fails this verification are dropped from the affected statistics rather than approximated. Comparisons across quote sets use the 976 cross sections solved to verified optimality under all four quote sets. Every statistic therefore conditions on a stated subsample of the 1,115 cross sections, and each table and figure reports its own counts.

5 What Do the Traded Quotes Reveal?

5.1 Main identified sets

Table 1 reports the main results. Under all retained OTM quotes, the median identified crash probability interval rises with the horizon, reaching 1.97 to 4.53 percent at 37 days. Even after every retained OTM

Table 1: Physical crash risk and the information in SPX option quotes

<i>Panel A: Main identified sets</i>					
Horizon	Cross sections	OTM quotes	$q_{2,K}$	$\ell_{2,K}$	$s_{2,K}$
23 days	402	105.0	[0.71, 2.11]	[0.047, 0.061]	[2.44, 7.35]
30 days	372	144.0	[1.42, 3.29]	[0.086, 0.105]	[2.81, 7.00]
37 days	324	95.5	[1.97, 4.53]	[0.127, 0.152]	[2.94, 7.44]

<i>Panel B: Median widths and reductions</i>					
Horizon	Put pair	Local eight	Put wing	All OTM	Total reduction [95% CI]
23 days	7.05	1.86	1.39	1.34	79.9 [78.4, 81.7]
30 days	12.14	2.87	1.91	1.82	84.4 [82.9, 85.3]
37 days	13.80	3.42	2.50	2.36	81.8 [80.3, 83.0]

<i>Panel C: Marginal source of probability identification</i>				
Added quote layer	23 days	30 days	37 days	
Pair to local eight	69.6 [66.1, 72.0]	72.2 [69.1, 74.8]	72.5 [70.2, 75.0]	
Local eight to put wing	28.0 [25.9, 31.0]	35.2 [32.7, 36.9]	26.9 [25.3, 28.4]	
Put wing to all OTM	2.6 [2.2, 3.3]	4.2 [3.3, 5.2]	5.0 [4.1, 6.4]	

Notes: One S&P 500 cross section per week and horizon, January 2013 through August 2023. All results use $\gamma = 2$, $K = 0.90$, $B = 5$, and each cross section's fixed discounting and forward. Panel A reports the number of cross sections, median retained OTM quote counts, and medians of interval endpoints across cross sections, in percent. The $s_{2,K}$ medians use 402, 371, and 324 cross sections. Panel B reports median interval widths for the crash probability, in percentage points, and the median proportional reduction from the put pair to all OTM quotes, in percent. Panel C reports median proportional reductions relative to the preceding quote set, in percent. Brackets are 95 percent calendar-week block bootstrap intervals.

quote is used, the upper endpoint remains two to three times the lower endpoint, so the quotes still admit economically different assessments of the same event.

Conditional depth is identified less tightly, with median intervals spanning roughly 2.4 to 7.4 percent of additional decline below the 10 percent threshold. The contrast between the two coordinates is not specific to this event definition: at $K = 0.85$ the probability intervals are narrower and the depth intervals wider, with the same ordering of quote-set contributions (Appendix C).

Panel B of Table 1 shows how much ambiguity remains under each quote set. All retained OTM quotes cut the put-pair widths by a median of 80 to 84 percent across horizons, and the bootstrap intervals are narrow relative to these magnitudes.

5.2 Physical crash risk over time

Figure 1 plots the all-OTM probability intervals by horizon. They rise in every major stress episode of the sample. The width often rises with the level: both endpoints move sharply upward around the COVID-19 episode at every horizon, so stress raises the implied crash risk and, at the same time, the range of crash probabilities the quotes admit.

5.3 Where the identifying information comes from

Figure 2 separates the level of the remaining ambiguity from the contribution of each quote layer. The largest change occurs when the six additional nearby puts join the put pair, the rest of the put wing remains informative, and OTM calls add little beyond the complete put wing (Table 1, Panel C). The identification

Figure 1: Time variation in quote-compatible physical crash probabilities. Shaded bands are weekly identified intervals for the physical probability of $X \leq 0.90$, in percent, under the benchmark kernel and all retained OTM quotes. The cross sections cover exact horizons of 23, 30, and 37 days with 402, 372, and 324 cross sections. Missing weeks appear as gaps. Results use $\gamma = 2$ and $B = 5$.

of a 10 percent decline therefore comes mainly from put prices, with the strongest contribution near the threshold.

These are marginal contributions along the nested sequence, and a reverse exercise confirms the same concentration: deleting the far put wing from the full quote set widens the median interval, deleting the OTM calls barely moves it, and deleting the six nearby puts leaves the median width unchanged, because neighboring wing strikes substitute for them. Finally, the quoted intervals themselves anchor the identification: doubling every bid–ask spread moves the endpoints an order of magnitude more than retaining only every other strike. Appendix C reports the magnitudes.

5.4 The unobserved right tail

The main specification places X in $[0, 5]$. Figure 3 compares that choice with tighter and looser support conditions on a fixed robustness subsample of 180 cross sections, 60 per horizon. The subsample is spaced evenly over the sample period and includes cross sections adjacent to the August 2015, February 2018, March 2020, and June 2022 stress dates. For finite caps between two and ten, the results are nearly unchanged.

Removing the cap acts on the probability bound alone. Without a support cap, the lower endpoint of the closed interval for $q_{2,K}$ is zero in every subsample cross section, as Proposition 3.6 predicts

Figure 2: Identification gains across nested quote sets. Panel A reports the median width of the identified crash probability interval under each quote set and horizon, in percentage points. Panel B reports the median proportional reduction relative to the preceding quote set, in percent. Results use $\gamma = 2$, $K = 0.90$, and $B = 5$.

Figure 3: Tail dependence of crash probability and conditional depth. The robustness subsample contains 180 cross sections, 60 at each horizon. The blue series reports the median ratio $q_{2,K}^-(B)/q_{2,K}^-(5)$, where $q_{2,K}^-(B)$ is the probability lower endpoint under support cap B . The gray dashed series reports the median ratio of conditional depth interval widths. Finite caps use all retained OTM quotes. Moving from $B = 2$ to $B = 10$ lowers a cross section's probability lower bound by a median of 0.0008 percentage points and by 0.0053 at the 95th percentile. The unbounded point reports the optimal values of the unbounded program: the probability lower endpoint is zero, and the largest depth width ratio relative to $B = 5$ is 1.0002. Results use $\gamma = 2$ and $K = 0.90$.

(Appendix A states the unbounded variant of the program). The conditional depth interval has no global-moment denominator, and its width barely moves.

6 Jointly Attainable Crash Scenarios

The four marginal endpoints are generally driven by four different measures, so a probability and shortfall pair drawn from the marginal rectangle may describe no single admissible distribution. This section examines the physical crash frontiers, first for selected cross sections and then for the full sample. Each plotted frontier follows the construction of Section 3.4, with the direction grid refined until the envelope is accurate to within one percent of the cross section's put-pair scale (Appendix C).

Figure 4 covers four prespecified 30-day market states, each matched to the closest admissible cross section: the 2015 selloff, a calm market in late 2019, the COVID-19 crash, and the 2022 selloff. The identified sets contract in the same order in every cross section. Two puts leave a large range of probability–shortfall combinations, nearby puts remove most of that range, and the complete put wing

Figure 4: Joint probability–shortfall sets across market states. Each cross section overlays the supporting half-plane envelopes of $\Theta_{qt}(\mathcal{I})$ for the put pair, local eight, complete put wing, and all OTM quotes. Each successive envelope intersects all half planes accumulated through that layer, so the sets are nested by construction. Probability and unconditional shortfall are in percent, at a 30-day horizon with $\gamma = 2$, $K = 0.90$, and $B = 5$. The cross section dates are 26 August 2015, 4 December 2019, 25 March 2020, and 8 June 2022. The COVID-19 and 2022 targets were 18 March 2020 and 15 June 2022. Each cross section uses its own axes.

and the OTM calls leave a much smaller set. The location of the surviving set tracks market conditions. The calm-market set lies close to the origin, and the 2015 and COVID-19 sets allow larger probability and shortfall values.

Figure 5 repeats the exercise across maturities around the COVID-19 crash. The 37-day set reaches the largest shortfall values among the three and has a broad probability range under sparse quotes. Additional puts contract the feasible region at every horizon, and the remaining all-OTM sets still differ in level and shape.

Across the 976 cross sections shared by the four quote sets, the joint restriction is strongest where shortfall is stressed. In the two directions that place positive weight on shortfall, the horizon-level median gaps between the all-OTM joint set and its marginal rectangle run from 2.7 to 4.0 percent of the put-pair scale (Appendix C.4). The same directional statistics show where each quote layer acts: nearby puts deliver most of the contraction in high-probability directions, while the rest of the put wing dominates in low-probability directions.

Figure 5: Joint probability–shortfall sets near the COVID-19 crash. Each cross section overlays the supporting half-plane envelopes for the put pair, local eight, complete put wing, and all OTM quotes at one horizon. Probability and unconditional shortfall are in percent. The panels use the closest admissible 23-, 30-, and 37-day observations around the 18 March 2020 target, dated 11 March, 25 March, and 18 March 2020. Results use $\gamma = 2$, $K = 0.90$, and $B = 5$. The vertical scales differ across cross sections.

7 Conclusion

Finite option quotes are informative about short-horizon physical crash risk. Mapping every quote-compatible distribution through the power utility investor’s pricing kernel separates what traded prices imply from what interpolation and tail assumptions add. In the S&P 500 cross sections studied here, most of the width of the put-pair probability interval disappears once all retained OTM quotes are used, with the largest contribution from puts near the threshold, and the sets rise and widen together during market stress.

Under the $\gamma = 2$ benchmark, crash probability depends on a global second moment that traded quotes leave unrestricted far in the tail, so removing the support cap drives the probability lower bound to zero, an exposure that opens precisely when risk aversion exceeds that of the log investor (Remark 3.7). The denominator cancels from conditional depth, and its interval is stable across the support conditions we examine. A positive lower bound on crash probability is therefore a joint statement about traded prices and the maintained support condition.

The physical crash frontier turns this evidence into a discipline for scenario analysis. It retains only the probability and shortfall combinations that a single admissible distribution can generate or approach, and its exclusions are strongest where scenarios stress shortfall. Under the maintained benchmark, event, and support conditions, any estimate that completes the surface while pricing the same quotes within their spreads must imply physical crash risk inside the frontier.

A Proofs and Complete Programs

A.1 Positive-return and threshold closure

Lemma A.1 (Approximation away from zero). *Under Assumption 3.3, every $\mathbb{Q} \in \mathcal{M}(I)$ is the weak limit of quote-compatible measures supported on $(0, B]$. For every fixed $r > 0$, their global and truncated r th moments converge to those of $\mathbb{Q}$.*

Proof. Form the mixture $(1 - \delta_\varepsilon)\mathbb{Q} + \delta_\varepsilon\mathbb{Q}^\circ$, where $\delta_\varepsilon \rightarrow 0$ and $\varepsilon/\delta_\varepsilon \rightarrow 0$. Move all mass at zero in the mixture to $\varepsilon > 0$. This preserves total mass and changes the mean and each retained option value by $O(\varepsilon)$. A transfer of order $O(\varepsilon)$ between U_+ and U_- restores the mean. The mass available in these intervals is of order δ_ε , so the transfer preserves nonnegativity for small ε . Strict quote slack inherited from the mixture absorbs the remaining payoff changes.

The resulting measures have strictly positive support. On $[0, B]$, the functions x^r are uniformly continuous for every $r > 0$, and the shifted zero-state contribution is $O(\varepsilon^r)$. The global and truncated moments therefore converge. $\square$

A.2 Proof of Theorem 3.2

Convexity and compactness of the joint set. For an admissible measure $\mathbb{Q}_j$, let $d_j = M_\gamma(\mathbb{Q}_j) > 0$, and set

$$\mathbf{n}_j = \begin{pmatrix} A_\gamma(\mathbb{Q}_j) \\ KA_\gamma(\mathbb{Q}_j) - A_{\gamma+1}(\mathbb{Q}_j) \end{pmatrix},$$

so that the probability–shortfall image of $\mathbb{Q}_j$ is $\mathbf{w}_j = \mathbf{n}_j/d_j$. Fix $\theta \in [0, 1]$ and define

$$\alpha = \frac{\theta d_1}{\theta d_1 + (1 - \theta)d_0}.$$

The mixture $\mathbb{Q}_\alpha = \alpha\mathbb{Q}_0 + (1 - \alpha)\mathbb{Q}_1$ is admissible because the quote and moment restrictions are linear in the measure, and

$$\frac{\alpha\mathbf{n}_0 + (1 - \alpha)\mathbf{n}_1}{\alpha d_0 + (1 - \alpha)d_1} = \theta\mathbf{w}_0 + (1 - \theta)\mathbf{w}_1.$$

The attainable image is therefore convex, and its closure is convex and nonempty. Since $\ell_{\gamma,K} = q_{\gamma,K}s_{\gamma,K}$ with $s_{\gamma,K} \in [0, K]$ whenever $q_{\gamma,K} > 0$, the closure is contained in $\{(q, \ell) : 0 \leq q \leq 1, 0 \leq \ell \leq Kq\}$. It is closed and bounded, hence compact. $\square$

The conditional depth interval. Let $\mathcal{M}_+ = \{\mathbb{Q} \in \mathcal{M}(\mathcal{I}) : A_\gamma(\mathbb{Q}) > 0\}$, a convex set. For $\mathbb{Q}_0, \mathbb{Q}_1 \in \mathcal{M}_+$ and $\alpha \in [0, 1]$, the mixture $\mathbb{Q}_\alpha = \alpha\mathbb{Q}_0 + (1 - \alpha)\mathbb{Q}_1$ satisfies

$$s_{\gamma,K}(\mathbb{Q}_\alpha) = \frac{\alpha A_\gamma(\mathbb{Q}_0)s_{\gamma,K}(\mathbb{Q}_0) + (1 - \alpha)A_\gamma(\mathbb{Q}_1)s_{\gamma,K}(\mathbb{Q}_1)}{\alpha A_\gamma(\mathbb{Q}_0) + (1 - \alpha)A_\gamma(\mathbb{Q}_1)}.$$

As α varies, this expression spans the interval between $s_{\gamma,K}(\mathbb{Q}_0)$ and $s_{\gamma,K}(\mathbb{Q}_1)$. The image is therefore an interval contained in $[0, K]$, and its closure is a nonempty compact interval, which is $\Theta_s^\gamma(\mathcal{I})$. $\square$

A.3 Threshold bookkeeping and the depth programs

Let h index the cell beginning at K . In the program of Section 3.4, the moment conditions on this cell apply to the residual moments

$$\bar{y}_{0h} = y_{0h} - \tilde{a}_K, \quad \bar{y}_{1h} = y_{1h} - K\tilde{a}_K, \quad \bar{y}_{2h} = y_{2h} - K^2\tilde{a}_K,$$

which satisfy (17)–(18) with $a = K$ and $b = b_{h+1}$, together with $\tilde{a}_K \geq 0$. The atom is part of y_{rh} , so it enters the global constraints (14) and the quote values (15) without further adjustment, while the targets (19) count it as event mass. An empty sum in (15) is interpreted as zero when $k_i \geq B$. When the support cap is removed, the terminal cell becomes a half line and keeps the positive semidefinite moment condition and the lower location inequality, while the upper support inequalities are dropped.

Conditional depth uses a second normalization. When $A_2(\mathbb{Q}) > 0$, define $\lambda = A_2(\mathbb{Q})^{-1}$ and $d\widehat{\mathbb{Q}} = \lambda d\mathbb{Q}$. The mass, forward, and truncated second-moment restrictions become

$$\int d\widehat{\mathbb{Q}} = \lambda, \quad \int X d\widehat{\mathbb{Q}} = \lambda, \quad \int_{[0,K]} X^2 d\widehat{\mathbb{Q}} = 1, \quad (22)$$

each quote band is multiplied by λ , and the objective is linear:

$$s_{2,K} = \int_{[0,K]} (K - X) X^2 d\widehat{\mathbb{Q}}. \quad (23)$$

With cell moments $\widehat{y}_{r,j} = \int x^r d\widehat{\mu}_j$ taken from a local decomposition of $\widehat{\mathbb{Q}}$, and with $\widehat{a}_K \geq 0$ the scaled event atom, the finite constraints are

$$\sum_j \widehat{y}_{0j} = \lambda, \quad \sum_j \widehat{y}_{1j} = \lambda, \quad \sum_{j \in \mathcal{J}_-} \widehat{y}_{2j} + K^2 \widehat{a}_K = 1, \quad (24)$$

$$\widehat{C}_i(\widehat{\mathbf{y}}) = \sum_{j: b_j \geq k_i} (\widehat{y}_{1j} - k_i \widehat{y}_{0j}), \quad \lambda \underline{c}_i \leq \widehat{C}_i(\widehat{\mathbf{y}}) \leq \lambda \bar{c}_i, \quad (25)$$

with the same cellwise moment cones and threshold treatment as before, and the linear objective

$$s_{2,K} = \sum_{j \in \mathcal{J}_-} (K \widehat{y}_{2j} - \widehat{y}_{3j}). \quad (26)$$

No global second-moment normalization is imposed. Unlike ρ , the scalar λ has no upper bound, so the depth programs need not attain their optimal values. The argument below shows that those values equal the endpoints of the closed depth interval.

A.4 Proof of Corollary 3.4

Proof. The feasible region is compact. It is closed, being cut out by finitely many linear equalities and inequalities and by second-order cone constraints. For boundedness, fix a feasible point. The cellwise moment conditions are sufficient, so the cell moments, net of the designated atom on the threshold cell, are moments of nonnegative measures on the closed cells. Summing the cells and adding the atom yields a nonnegative measure on $[0, B]$ with total mass ρ , first moment ρ , and second moment one. The Cauchy–Schwarz inequality gives $\rho^2 \leq \rho \cdot 1$, so $\rho \leq 1$, and the bounded support gives $0 \leq y_{r,j} \leq B^r y_{0j} \leq B^r$ for every stored order together with $0 \leq \widetilde{a}_K \leq y_{0h} \leq 1$. Every coordinate of a feasible point is therefore bounded.

We now show two inclusions: the attainable image maps into the feasible region, and every feasible point is the limit of attainable pairs. Together with the compactness just established and the linearity of the targets, these give the equality of $\Theta_{q\ell}(\mathcal{I})$ and the conic image, and the support values follow by linear optimization over the same set.

First take any admissible $\mathbb{Q}$ and set $\rho = M(\mathbb{Q})^{-1} \in [1/B, 1]$ and $d\widetilde{\mathbb{Q}} = \rho d\mathbb{Q}$. Decompose $\widetilde{\mathbb{Q}}$ into local components, assigning the atom at K , if any, to the cell beginning at K , and let $\widetilde{a}_K$ be that scaled atom. The resulting $(\mathbf{y}, \rho, \widetilde{a}_K)$ satisfies every constraint: the global equalities are (12), the quote inequalities are the scaled quote bands, the cells below K carry genuine moment sequences of measures on closed intervals, and the threshold cell satisfies its conditions net of the designated atom. The targets (19) equal $(q_{2,K}(\mathbb{Q}), \ell_{2,K}(\mathbb{Q}))$ by (8).

Conversely, take any feasible $(\mathbf{y}, \rho, \widetilde{a}_K)$. The truncated Hausdorff conditions supply, cell by cell, a nonnegative measure on the closed cell with the prescribed moments. Adding the designated atom $\widetilde{a}_K$ at K and summing the cells produces a nonnegative measure $\widetilde{\mathbb{Q}}'$ that satisfies the mass, forward, second-moment, and quote restrictions, since each restriction is an integral of a continuous function against the cell moments. Where a reconstructed cell measure places mass at a shared endpoint $b_j \neq K$, the location is unambiguous relative to the threshold, so neither the constraints nor the targets are affected by which cell carries it. The support inequalities give $1 = \sum_j y_{2j} \leq B \sum_j y_{1j} = B\rho$, so $\rho \geq 1/B > 0$, and the measure $d\mathbb{Q}' = d\widetilde{\mathbb{Q}}'/\rho$ has mass one, mean one, second moment $1/\rho$, and satisfies every quote interval.

One discrepancy can remain: the reconstruction of the cell beginning at K may itself place mass at K beyond the designated atom, whereas the targets (19) treat that residual mass as lying above the threshold.

Move the residual mass to $K + \varepsilon$ and correct the measure with the mixing construction of Lemma A.1: blend in weight δ_ε of the interior measure $\mathbb{Q}^\circ$, transfer order ε between U_- and U_+ to restore the mean, and use the inherited strict quote slack to keep every quote value inside its interval for small ε . The resulting measures $\mathbb{Q}_\varepsilon$ are admissible, and their probability and shortfall converge to the targets of the feasible point. Every feasible point is therefore attained or approached, and the conic image, which is compact because the feasible region is compact and the map is linear, equals the closed set $\Theta_{q\ell}(\mathcal{I})$.

For the depth programs, let S denote the set of attainable conditional depths and V the set of objective values of feasible points. Any admissible $\mathbb{Q}$ with $A_2(\mathbb{Q}) > 0$ produces a feasible pair $(\hat{y}, \lambda)$ with $\lambda = A_2(\mathbb{Q})^{-1}$ whose objective value is $s_{2,K}(\mathbb{Q})$, so $S \subseteq V$. Conversely, every feasible point carries a finite scalar λ , which the unit constraint in (24) forces to be positive. If its threshold-cell reconstruction carries no residual mass at K , dividing $\hat{\mathbb{Q}}$ by λ yields an admissible measure with $A_2 = 1/\lambda$ whose conditional depth equals the objective (26). In general, the same $K + \varepsilon$ construction yields admissible measures whose depths converge to the objective value. Every value in V is therefore a limit of values in S , and

$$S \subseteq V \subseteq \text{cl } S = \Theta_s(\mathcal{I}).$$

Suprema and infima agree across this chain, so the optimal values of the two conic programs equal the endpoints of the compact interval $\Theta_s(\mathcal{I})$. These optimal values need not be attained by feasible points: when $A_2 \downarrow 0$ along a sequence of admissible measures, λ diverges, and no feasible point need exist whose objective value equals the endpoint. $\square$

A.5 Proof of Proposition 3.6

Proof. Let ν_- and ν_+ be the conditional distributions of $\mathbb{Q}^\circ$ on U_- and U_+ , with means $\mu_- < 1 < \mu_+$. For H above the retained strikes and U_+ , set

$$\varepsilon_H = H^{-3/2}, \quad a_H = \varepsilon_H \frac{H - \mu_+}{\mu_+ - \mu_-}, \quad b_H = \varepsilon_H \frac{H - \mu_-}{\mu_+ - \mu_-}.$$

Let δ_H denote unit mass at H , and define

$$\mathbb{Q}_H = \mathbb{Q}^\circ + \varepsilon_H \delta_H + a_H \nu_- - b_H \nu_+.$$

The coefficients satisfy $\varepsilon_H + a_H - b_H = 0$ and $\varepsilon_H H + a_H \mu_- - b_H \mu_+ = 0$, so $\mathbb{Q}_H$ has mass one and mean one. Since $b_H \rightarrow 0$ and $\mathbb{Q}^\circ(U_+) > 0$, the measure is nonnegative for all sufficiently large H .

For a retained call payoff $h_i(x) = (x - k_i)^+$,

$$\mathbb{E}_{\mathbb{Q}_H}[h_i(X)] - \mathbb{E}_{\mathbb{Q}^\circ}[h_i(X)] = \varepsilon_H h_i(H) + a_H \mathbb{E}_{\nu_-}[h_i(X)] - b_H \mathbb{E}_{\nu_+}[h_i(X)] = O(H^{-1/2}).$$

There are finitely many quotes, so strict interior slack implies that $\mathbb{Q}_H$ satisfies every quote interval for all sufficiently large H . The intervals U_- and U_+ are bounded, so

$$M(\mathbb{Q}_H) = M(\mathbb{Q}^\circ) + \varepsilon_H H^2 + O(H^{-1/2}) = M(\mathbb{Q}^\circ) + H^{1/2} + O(H^{-1/2}) \rightarrow \infty.$$

Finally, $A_2(\mathbb{Q}_H) \leq K^2$, and since $K - X \leq K$ on the event, also $KA_2(\mathbb{Q}_H) - A_3(\mathbb{Q}_H) \leq KA_2(\mathbb{Q}_H) \leq K^3$. Hence

$$0 \leq q_{2,K}(\mathbb{Q}_H) \leq \frac{K^2}{M(\mathbb{Q}_H)} \rightarrow 0, \quad 0 \leq \ell_{2,K}(\mathbb{Q}_H) \leq \frac{K^3}{M(\mathbb{Q}_H)} \rightarrow 0,$$

so the probability–shortfall pair of $\mathbb{Q}_H$ converges to the origin, which therefore lies in the closure of the joint image. $\square$

B The Log-Investor Benchmark

B.1 Mathematical specialization

When $\gamma = 1$, the forward restriction fixes the denominator of the transform (4) at $M_1(\mathbb{Q}) = \mathbb{E}_{\mathbb{Q}}[X] = 1$, so the dilution channel of Proposition 3.6 is absent and the tail acts only through the quote and forward restrictions (Remark 3.7). The probability and unconditional shortfall are therefore linear in the unscaled measure,

$$q_{1,K}(\mathbb{Q}) = A_1(\mathbb{Q}), \quad \ell_{1,K}(\mathbb{Q}) = KA_1(\mathbb{Q}) - A_2(\mathbb{Q}), \quad (27)$$

and, when $A_1(\mathbb{Q}) > 0$, conditional depth is $s_{1,K}(\mathbb{Q}) = K - A_2(\mathbb{Q})/A_1(\mathbb{Q})$. No change of scale is needed for the joint set. Use the same cells as Section 3.4 and a local decomposition $\mathbb{Q} = \sum_j \mu_j$, with strike-endpoint atoms assigned to either adjacent cell and any atom at K assigned to the cell beginning at K . For each μ_j , define the cell mass z_j and first moment m_j , together with the second moment v_j on the cells whose interiors lie below K . The global restrictions are

$$\sum_j z_j = 1, \quad \sum_j m_j = 1. \quad (28)$$

Cells below the threshold carry the complete order-two conditions (17)–(18) in (z_j, m_j, v_j) . Cells at or above K need only $az_j \leq m_j \leq bz_j$. With h the cell beginning at K and a_K the threshold mass assigned to the closed event,

$$0 \leq a_K \leq z_h, \quad m_h \leq b_{h+1}z_h - (b_{h+1} - K)a_K, \quad (29)$$

each quote value is linear as in (15) with (z_j, m_j) in place of (y_{0j}, y_{1j}) and unscaled bands, and the targets are

$$q_{1,K} = \sum_{j < h} m_j + Ka_K, \quad \ell_{1,K} = \sum_{j < h} (Km_j - v_j). \quad (30)$$

Under Assumption 3.3, the same closure argument as in Appendix A.4 identifies this feasible region with the closed log-investor joint set. Conditional depth again uses a second normalization: with $\lambda = A_1(\mathbb{Q})^{-1}$ and $d\widehat{\mathbb{Q}} = \lambda d\mathbb{Q}$, the mass and forward integrals both equal λ , the unit constraint is $\int_{[0,K]} X d\widehat{\mathbb{Q}} = 1$, and the objective $\int_{[0,K]} (K - X)X d\widehat{\mathbb{Q}}$ is linear. The scaled quote bands, cell moment conditions, and threshold-atom treatment carry over from Appendix A.3, with first and second moments in the roles that second and third moments play there.

B.2 Comparison with the $\gamma = 2$ kernel

Proposition B.1 (Kernel comparison). *Fix $K \in (0, 1)$ and consider a common quote-compatible domain of unit-mean measures with finite second moments. For every $\mathbb{Q}$ in this domain with positive truncated moments,*

$$q_{2,K}(\mathbb{Q}) \leq Kq_{1,K}(\mathbb{Q}) \leq q_{1,K}(\mathbb{Q}), \quad \ell_{2,K}(\mathbb{Q}) \leq K\ell_{1,K}(\mathbb{Q}), \quad s_{2,K}(\mathbb{Q}) \leq s_{1,K}(\mathbb{Q}). \quad (31)$$

Proof. On the event $X \leq K$, $X^2 \leq KX$. Also $M(\mathbb{Q}) \geq M_1(\mathbb{Q})^2 = 1$. Hence

$$q_{2,K} = \frac{A_2}{M(\mathbb{Q})} \leq A_2 \leq KA_1 = Kq_{1,K} \leq q_{1,K}.$$

The same argument applied to $(K - X)X^2 \leq K(K - X)X$ gives $\ell_{2,K} \leq K\ell_{1,K}$. The truncated moment sequence is log-convex, so $A_2^2 \leq A_1A_3$. Dividing by $A_1A_2 > 0$ and subtracting from K gives $s_{2,K} \leq s_{1,K}$. $\square$

Taking extrema in (31) compares corresponding endpoints: each $\gamma = 2$ probability and shortfall endpoint lies below K times its $\gamma = 1$ counterpart, and each depth endpoint lies below its counterpart on the common positive-probability domain. The inequalities impose no cross-endpoint ordering, and the optimizing measures can differ.

Table 2: Kernel comparison on common cross sections

Horizon	Cross sections	q width		ℓ width		s width	
		$\gamma = 1$	$\gamma = 2$	$\gamma = 1$	$\gamma = 2$	$\gamma = 1$	$\gamma = 2$
23 days	405	1.54	1.40	0.017	0.013	4.93	4.81
30 days	369	2.08	1.88	0.024	0.017	4.27	4.10
37 days	332	2.57	2.35	0.033	0.023	4.54	4.26

Notes: Median interval widths in percentage points, computed on the cross sections where both kernels solve, under all retained OTM quotes, $K = 0.90$, $B = 5$, and each cross section's fixed discounting and forward.

Table 3: Identified sets for a 15 percent decline

Horizon	Cross sections	Median $q_{2,K}$	q width	Depth cross sections	s width
23 days	404	[0.14, 0.70]	0.53	393	9.98
30 days	373	[0.33, 1.08]	0.76	362	7.70
37 days	330	[0.47, 1.61]	1.07	329	8.07

Notes: All retained OTM quotes, $K = 0.85$, $B = 5$. Probability entries are medians of interval endpoints across cross sections, in percent. Width entries are median interval widths, in percentage points. Depth widths use the cross sections whose closed probability interval excludes zero.

B.3 Full-sample comparison

Table 2 reports both kernels on the same cross sections, the same event $K = 0.90$, the same support cap $B = 5$, and the same all-OTM quote sets. The sample keeps the cross sections where both kernels' programs solve, a criterion that differs from the verification behind Table 1, so the counts differ slightly. The $\gamma = 2$ intervals are narrower for every coordinate at every horizon. Proposition B.1 orders endpoint levels and is silent about widths, so the width ordering is an empirical regularity. The two kernels nonetheless agree on how identification varies across horizons and coordinates.

C Supplementary Evidence

C.1 A more extreme threshold

Table 3 repeats the all-OTM analysis at $K = 0.85$. The probability intervals are narrower than at $K = 0.90$ and the conditional depth intervals are wider: a more extreme event can have a narrow probability range and a wide range of depth conditional on occurring. The quote layers contribute in the same order as at the main threshold: adding the six nearby puts cuts the median put-pair widths by 70 to 75 percent, and the complete put wing and the calls deliver the remaining contraction to the widths in the table.

C.2 Quote perturbations and deletions

Two exercises alter the information content of the quotes on a prespecified subset of 24 cross sections from the robustness subsample. Doubling every bid–ask spread around its midpoint changes a probability endpoint by a median of 0.79 percentage points and a conditional depth endpoint by a median of 1.84 percentage points. Retaining every other strike changes the corresponding endpoints by medians of 0.073 and 0.122 percentage points.

A reverse decomposition deletes groups of quotes from the full OTM set on the robustness subsample of 180 cross sections. Removing the put wing beyond the local eight widens the median probability interval by 0.46, 0.76, and 0.52 percentage points at the three horizons. Removing all OTM calls widens it by 0.05, 0.08, and 0.13 percentage points. Removing the six nearby puts while keeping every other quote leaves the median width unchanged, because the neighboring wing strikes substitute for them. Marginal

Table 4: Verification of the regularity condition by cross section

Horizon	Cross sections	Verified	Rate (%)	Median slack ($\times 10^{-5}$)
23 days	406	405	99.8	1.1
30 days	376	374	99.5	1.1
37 days	333	332	99.7	1.5

Notes: A cross section is verified when an admissible measure prices every retained quote strictly inside its bid–ask interval and places mass on both sides of the forward away from strike and threshold boundaries. Slack is the smallest distance from a constructed option value to its quote endpoints, in normalized price units.

contributions therefore depend on the base set: nearby puts carry most of the information relative to the sparse pair, and the wing carries unique information that survives even when the local strikes are dense.

C.3 Verification of the regularity condition

Table 4 summarizes the verification of Assumption 3.3 in each cross section, described in Section 4.3. The verification fails only in the 23- and 37-day cross sections of 20 January 2016 and the 30-day cross sections of 31 May 2017 and 7 September 2022.

C.4 Directional joint restrictions

Let q_{pair}^- and ℓ_{pair}^- be the put-pair lower endpoints of a cross section, and let w_q^{pair} and w_ℓ^{pair} be the positive put-pair widths. Joint comparisons use the normalized coordinates

$$\bar{q} = \frac{q - q_{\text{pair}}^-}{w_q^{\text{pair}}}, \quad \bar{\ell} = \frac{\ell - \ell_{\text{pair}}^-}{w_\ell^{\text{pair}}}. \quad (32)$$

Let $\bar{\Theta}$ be the normalized joint set, $\bar{\mathcal{R}}$ its marginal rectangle, and $H_{\mathcal{A}}(d) = \sup_{z \in \mathcal{A}} d^\top z$ the support function of a set $\mathcal{A}$ in direction d . For the four diagonal directions

$$\mathcal{D} = \left\{ \frac{(1,1)}{\sqrt{2}}, \frac{(1,-1)}{\sqrt{2}}, \frac{(-1,1)}{\sqrt{2}}, \frac{(-1,-1)}{\sqrt{2}} \right\},$$

the normalized support gap and the directional contraction between nested quote sets $\mathcal{A} \subseteq \mathcal{B}$ are

$$g(d) = 100 \left[H_{\bar{\mathcal{R}}}(d) - H_{\bar{\Theta}}(d) \right], \quad c_{\mathcal{A} \rightarrow \mathcal{B}}(d) = 100 \left[H_{\bar{\Theta}^{\mathcal{A}}}(d) - H_{\bar{\Theta}^{\mathcal{B}}}(d) \right]. \quad (33)$$

Figure 6 summarizes these statistics on the 976 cross sections shared by the four quote sets. The gap between the joint set and its marginal rectangle concentrates in the two directions that place positive weight on shortfall, where the horizon-level median gaps run from 2.7 to 4.0 percent of the put-pair scale. Pooling all four directions, the median all-OTM gap is 0.52 percent. The contraction statistics show where each layer acts. Moving from the pair to the local eight produces the largest contractions in high-probability directions, with medians of 33 and 51 percent of the pair scale, while moving from the local eight to the complete put wing dominates in low-probability directions, with medians of 8 and 43 percent. The median contraction from the put pair to the all-OTM set across the four directions is 50 percent of the pair scale.

C.5 Accuracy of the plotted joint sets

The joint sets of Section 6 are drawn as intersections of supporting half planes on an adaptive direction grid that doubles from 32 to at most 128 directions until the gap to the inner hull of support points falls below one percent of the put-pair scale. Table 5 reports the realized accuracy for each plotted cross section: the largest normalized gap across the four quote sets is at most 0.99 percent, so every plotted envelope is visually indistinguishable from the identified set at the resolution of the figures.

Figure 6: Directional joint restrictions and quote-set contraction. Panel A reports the median normalized support gap between the all-OTM joint set and its marginal rectangle in four prespecified directions. Panel B reports the median support contraction contributed by adjacent quote layers in the same directions. Both panels use each cross section's put-pair marginal widths for normalization and cover the 976 cross sections shared by the four quote sets. Results use $\gamma = 2$, $K = 0.90$, and $B = 5$.

Table 5: Adaptive-grid accuracy of the plotted joint sets

Figure cross section	Date	Horizon	Directions	Max gap (%)
2015 selloff	26 Aug 2015	30 days	128	0.80
Calm market	4 Dec 2019	30 days	128	0.93
COVID-19 crash	25 Mar 2020	30 days	128	0.90
2022 selloff	8 Jun 2022	30 days	128	0.98
COVID-19, 23 days	11 Mar 2020	23 days	128	0.76
COVID-19, 37 days	18 Mar 2020	37 days	64	0.99

Notes: For each plotted cross section, Directions is the largest adaptive grid level used across the four quote sets, and Max gap is the largest normalized support gap between the plotted outer polygon and the inner hull of its support points, in percent of the put-pair scale. The 30-day COVID-19 cross section appears in both Figures 4 and 5.
