Figure 1: **EAGOR** for geometry-aware embodied omni-directional reasoning (○ = Target)

Abstract: Omni-directional (360°) cameras enable embodied agents with a wide and holistic view of their surroundings, making them advantageous for directional reasoning in embodied tasks, such as navigation, and object search. Existing Vision Language Models (VLMs) project 360° data to 2D planar images via commonly used equirectangular projection (ERP) and process them with architectures designed for perspective images. However, they overlook the fact that 360° data is fundamentally spherical, with each pixel encoding a direction relative to the agent’s view. As a result, existing methods often produce direction estimates that are inconsistent under camera view transformation due to agent motion. This becomes critical in map-free navigation, where the agent must continuously update its direction to a target in its egocentric frame as it navigates in 360° environment. In this paper, we propose **EAGOR**, a **training-free** and **geometry-aware** framework for embodied 360° directional reasoning. **Our key idea** is to reframe the dynamic agent-to-target directional relationship from 360° observations as *recursive Bayesian estimation on the sphere*, rather than as pixel-coordinate prediction in an ERP image. EAGOR therefore maintains a continuous, geometrically correct belief to a target direction on the sphere, and propagating it equivariantly under agent motion, without training the backbone VLMs. To realize this formulation, we introduce a **Spherical Harmonic Belief Field (SH-BF)**, whose spherical harmonic representation provides a globally defined and rotation-aware basis for target direction estimation directly on the spherical manifold. As a result, EAGOR avoids the seam discontinuities, latitude distortions, and interpolation errors caused by the ERP. We evaluate EAGOR on two benchmark datasets and real-world experiments with a legged robot for multiple directional reasoning tasks. EAGOR consistently outperforms the baselines, achieving average relative gains of +34.4% and +45.6% on HOS and OSR-Bench, respectively, for active visual search. Notably, EAGOR improves navigation success by +14.6%, reducing steps counts by 17.7% and mean angular error by 24.5%.

1 Introduction

Directional reasoning – the fundamental ability to estimate, track, and update spatial vectors relative to the agent’s own physical posture – is a cornerstone of embodied AI. Just as humans rely on a continuous, multi-sensory awareness of their surroundings to track objectives even when looking away, a physical agent, like robot, must accurately compute the egocentric direction of a target and dynamically maintain it during ego-motion [1, 2, 3].

Omni-directional (360°) cameras capture full surrounding environment with a $180^\circ \times 360^\circ$ field-of-view (FoV), enabling agents to observe targets, landmarks, and obstacles in all directions [4, 5]. This makes them advantageous for directional reasoning in embodied AI tasks, such as map-free navigation and active visual search. In practice, spherical data is transmitted into 2D planar representations via equirectangular projection (ERP), *a.k.a.* panorama to preserve omni-directional information. However, ERP introduces seam discontinuities and latitude-dependent distortions, which violate the Euclidean assumptions built into the recent popular Vision-Language Models (VLMs), *e.g.*, [6]. Consequently, it causes spatial relations and direction estimates to be inconsistent due to camera transformations or agent motion [7, 8, 9, 10, 11].

Crucially, omni-directional reasoning represents the surrounding scene in terms of **viewing directions around the agent**, rather than positions on a flat image plane. For embodied omni-directional reasoning, the relevant output is therefore not only the **location** of a target, but also the **egocentric direction** the agent should turn, move, or search toward [12]. As illustrated in Fig. 2, projection-based representations can accumulate interpolation errors under camera rotation, causing the predicted target direction to drift over time. This reveals a representation gap in omni-directional reasoning. While VLM’s provide strong semantic observations in image space, the underlying geometry must be handled in a representation that respects the observer-centered geometry of the sphere.

For action, the agent needs a continuous egocentric direction to the target that remains consistent under motion, not merely a 2D pixel location in the panorama. A suitable framework should therefore satisfy two requirements: **(a)** represent target direction probabilistically on the sphere (Fig. 1d), and **(b)** propagate this state consistently as the agent moves and rotates (Fig. 1a,b). This motivates our research question: *Can VLMs perform geometry-aware omni-directional reasoning through a continuous belief representation over panoramic observations without task-specific training?*

To answer this, we introduce **EAGOR** (Embodied reASONinG in OMni-diREction), a **training-free** and **geometry-aware** embodied omni-directional reasoning framework. EAGOR decouples semantic perception from geometric state estimation. Instead of directly asking detectors or vision-language models to predict the final target direction, EAGOR uses them to extract target-conditioned evidence from the current panorama. The omni-directional inference is remodeled as belief estimation on the sphere. This evidence is lifted from projected image coordinates to viewing directions on the sphere and treated as an observation likelihood over possible target directions. We model this likelihood with a **Spherical Harmonic Belief Field (SH-BF)**, representing continuous directional belief in the SH domain (Sec. 3.2). This enables precise likelihood estimation required for accurate omni-directional reasoning while avoiding the artifacts caused by ERP, as shown in Fig. 1d.

We evaluate EAGOR across multiple embodied omni-directional reasoning tasks: *Waypoint Following* and *Map-free Navigation* in Habitat-Sim; *Active Visual Search* on HOS and OSR-Bench; and real-world *Dynamic Tracking* on a legged robot. Notably, for *Active Visual Search* (Fig. 1e), EAGOR achieves up to $\sim 1.5\times$ gain on HOS and over **35%** relative improvement with a **10 $\times$** smaller backbone on OSR-Bench. For *Map-free Navigation* (Fig. 1c), it reduces temporal inconsistency by $6.5\times$. Real-world results further demonstrate generalization of our training-free approach.

In summary, our contributions are: **(I)** We identify a critical representation gap in embodied omni-directional reasoning – robotic action requires a motion-consistent directional belief on the sphere (Fig. 2). **(II)** We propose EAGOR, a training-free and geometry-aware framework that models VLM-based semantic evidence as likelihood on the sphere for accurate omni-directional reasoning (Fig. 3). **(III)** We introduce SH-BF for representing continuous and rotation-consistent directional belief propagation under robot motion (Sec. 3.2). **(IV)** We validate EAGOR across multiple embodied omni-directional reasoning tasks and benchmarks, together with real-world validation on a legged robot, showing superior reasoning performance for navigation and visual search (Sec. 4.2).

Figure 2: **Qualitative results for Waypoint Following task.** (a) Initial target-direction estimate. (b) Directional estimates after viewpoint changes during waypoint following. *Qwen2.5-VL + EAGOR* ($\diamond$) consistently preserves the target direction under agent motion, whereas the centroid ($\circ$) and grid-based ($\square$) baselines drift due to accumulated ERP interpolation errors.

2 Related Works

Omni-directional Perception for Embodied Navigation. Early approaches address ERP distortions by decomposing panoramas into perspective crops and applying standard pretrained models [13, 11, 14], while recent methods incorporate panorama-aware attention, spherical positional encodings, or large-scale panoramic supervision [15, 16, 17, 18, 19]; yet benchmarks such as OSR-Bench and ODI-Bench reveal that MLLMs still struggle with reference-frame transformation [20, 21, 22, 23], indicating that semantic recognition does not guarantee geometric correctness: *a model may identify the target while estimating its direction incorrectly*. These limitations become critical in embodied applications such as navigation and active visual search, where the agent must dynamically maintain its egocentric target direction under motion. Instead of reasoning directly over sphere, prior methods typically depend on global reference frames, prebuilt maps, per-frame decisions from panoramic crops, or waypoint prediction in planar coordinates [24, 25, 26, 27, 28, 29]. Consequently, their directional estimates remain tied to representations that distort under egocentric rotation. *Our work therefore treats directional reasoning not as a recognition problem to be solved per frame, but as a geometric state estimation problem to be maintained continuously on the sphere.*

Probabilistic Evidence Accumulation for Direction Estimation. A deeper limitation of existing reasoning frameworks is they treat VLM spatial outputs as deterministic coordinate predictions, discarding the underlying uncertainty and using a single noisy or incorrect observation as a definitive answer [30, 25, 19]. Rather than explicitly modeling this uncertainty, prior approaches typically rely on repeated querying or confidence-based filtering [31, 32]. In embodied settings, direction estimation is inherently sequential: as the agent moves, the agent-to-target direction must be updated under egocentric rotation. We instead treat observations as probabilistic directional likelihood and accumulate them recursively over time [33, 34], forming a continuous belief over possible target directions on the sphere. This allows multiple plausible directions to be maintained and refined over time as new evidence is accumulated. Unlike prior probabilistic approaches [35, 36] operating in 2D planar image space, our framework maintains and updates this belief directly on the sphere.

Spherical Harmonic Representations. Spherical harmonics (SH) provides a equivariant representation for signals on $\mathbb{S}^2$ and have been widely adopted for equivariant feature learning, omni-directional learning tasks [37, 9, 38, 39], such as localization [40], depth estimation [39], and scene understanding [9]. However, all these works take SH representations as learned task-specific features [37, 38], or encoded analytic signals [39]. In this work, we leverage SH as a belief representation for recursive Bayesian estimation which incorporates noisy, open-vocabulary observations as directional likelihoods. *Our proposed SH-BF realizes the belief representation by connecting frozen VLM evidence to recursive spherical belief estimation, enabling geometrically consistent agent to target directional representation across embodied navigation and active visual search.*

3 Methodology

Overview. Fig. 3 illustrates the overview of the EAGOR framework. The key idea is to *decouple semantic perception from geometric state estimation*. Rather than predicting target direction as a pixel coordinate in an ERP image, EAGOR treats the agent-to-target direction as a continuous belief on the sphere. Given a panoramic observation I^t and a target query, a frozen VLM provides semantic evidence, which is lifted to the spherical domain and fused into a directional belief. To realize this,

Figure 3: **Overview of EAGOR framework.** See main texts of Sec.3 for details.

we introduce the **Spherical Harmonic Belief Field (SH-BF)**, which represents belief on $\mathbb{S}^2$ and supports consistent evidence accumulation, equivariant propagation under agent rotation, and MAP direction estimation. In short, the VLM identifies *what* to look for, while SH-BF maintains *where* the target lies relative to the agent at time t .

3.1 From panoramic observations to directional likelihoods

At each timestep t , the agent receives two inputs: a full 360° panoramic image I_t from its current viewpoint and a target query specifying the object of interest. The task is to estimate the egocentric agent-to-target direction $\omega_t^* \in S^2$, represented as a unit vector in the viewer-centric frame.

Given I_t and the query, the VLM produces a target-conditioned response map $\ell_t(u, v) \in [0, 1]$ over the ERP image, where each score indicates how likely the target is to appear at image location (u, v) . This target-conditioned response is the VLM’s spatially distributed attention patch to the query, interpreted as a directional likelihood field over viewing directions rather than a point prediction. As shown in Fig. 3, the response map may contain multiple candidate regions in image space, corresponding to several plausible target directions in the current panorama. Further details about detection and lifting is given in *Sec. 1.1 of Suppl. Mat.*

For an image of width W and height H , we map pixel coordinates to azimuth and elevation by $\theta = 2\pi u/W - \pi$ and $\phi = \pi/2 - \pi v/H$, giving the unit direction

$$\omega(u, v) = (\cos \phi \cos \theta, \cos \phi \sin \theta, \sin \phi). \quad (1)$$

Using this mapping, the image response $\ell_t(u, v)$ is converted into a directional likelihood field $\ell_t(\omega) : S^2 \rightarrow [0, 1]$. This field describes, for the current panorama alone, how likely each viewing direction is to contain the target. As shown in Fig. 3, lifting this response to the sphere converts the image-space candidates into directional likelihood peaks on S^2 , with their relative intensities reflecting the VLM’s confidence. The response map is normalized to $[0, 1]$ before the log transform. To combine evidence across multiple timesteps, we work in log space so that likelihood contributions from successive observations can be accumulated additively. We therefore convert the directional likelihood into a log-likelihood field $r_t(\omega) = \log(\ell_t(\omega) + \epsilon)$, where ϵ avoids numerical instability and pass it on for SH transform. We treat $r_t(\omega)$ as the current observation in the Bayesian estimator, i.e., the directional evidence provided by the current panorama at time t . In practice, this single-frame observation can be noisy due to false detections, occlusion, or ERP distortion. Therefore, EAGOR does not estimate the final target direction directly from one image. Instead, it treats target localization as a recursive state estimation problem on S^2 , where each panorama provides a new directional observation and the final estimate is obtained by accumulating evidence over time.

3.2 Spherical Harmonic Belief Field (SH-BF)

Given the current directional observation in log-likelihood form, $r_t(\omega)$, EAGOR maintains a persistent belief over possible target directions on the sphere. The required output is the egocentric target direction ω_t^* , while the belief summarizes what the agent has inferred about that direction from past observations and agent motion. We denote this belief as a continuous field $f_t : S^2 \rightarrow \mathbb{R}$.

Formally, $f_t(\omega)$ denotes the accumulated log-posterior score that the target lies in direction ω , : $f_t(\omega) \approx \log p(\omega^* = \omega \mid z_{1:t}, a_{1:t})$, where $r_t(\omega)$ is the directional evidence extracted only from the current panorama at timestep t , whereas $f_t(\omega)$ is the running belief obtained by recursively combining information over time. Refer to *Sec. 1.2 of Suppl. Mat.* for more details.

Figure 4: **Qualitative results for EAGOR using Qwen2.5-VL.** Direction reasoning during seam crossing (target: bed) where $\rightarrow$ indicates the EAGOR predicted direction, while $\rightarrow$ shows the erroneous direction produced by the centroid-based baseline. $\circ$ marks the belief centroid.

To support dynamic belief updates, the representation must satisfy two requirements: 1) it must accumulate evidence additively over time and 2) transform equivariantly under robot rotation. We thus represent the belief in the real SH basis, which provides a continuous representation on S^2 and allows both operations to be performed directly in coefficient space without ERP distortions:

$$f_t(\omega) = \sum_{\ell=0}^L \sum_{m=-\ell}^{\ell} c_{\ell m}^{(t)} Y_{\ell}^m(\omega), \quad (2)$$

where coefficients $c_{\ell m}^{(t)}$ represent the agent’s current belief state and $L = 7$ is the SH bandlimit. The observation $r_t(\omega)$ is projected onto the SH basis Y_{ℓ}^m to obtain coefficients $\mathbf{b}^{(t)}$, encoding evidence from the current panorama. Belief update is then carried out in coefficient space.

As shown in Fig. 3, at the first timestep, no prior belief is available. Thus, the first panorama produces observation coefficients $\mathbf{b}^{(1)}$, which directly initialize the posterior belief, i.e., $\mathbf{c}^{(1)} = \mathbf{b}^{(1)}$. For each subsequent timestep $t > 1$, the posterior belief from the previous step, $\mathbf{c}^{(t-1)}$, is carried forward as the previous belief state. After the robot moves from timestep $t - 1$ to t , this belief is rotated into the current viewer-centric frame to form the propagated prior $\tilde{\mathbf{c}}^{(t)}$. This prior is then combined with the current observation coefficients $\mathbf{b}^{(t)}$, obtained from the new panorama I_{t+1} to update the posterior belief $\mathbf{c}^{(t)}$. After an action is executed and transitioned to the next viewpoint, the posterior $\mathbf{c}^{(t)}$ is stored and becomes the previous posterior belief used at timestep $t + 1$.

Current observation in SH space. As illustrated in Fig. 3, the belief update proceeds through two branches. The upper branch converts the current panorama into observation coefficients $\mathbf{b}^{(t)}$, which encode the current directional evidence in SH space. The lower branch propagates the previous posterior belief $\mathbf{c}^{(t-1)}$ under the agent’s motion to obtain the prior coefficients $\tilde{\mathbf{c}}^{(t)}$. These two terms are then fused additively to form the updated posterior belief $\mathbf{c}^{(t)}$, which is decoded into the final direction estimate. To incorporate the current panorama, we project the log-likelihood field $r_t(\omega)$ onto the same SH basis. This yields the observation coefficients $\mathbf{b}^{(t)} = \{b_{\ell m}^{(t)}\}$:

$$b_{\ell m}^{(t)} = \int_{S^2} r_t(\omega) Y_{\ell}^m(\omega) d\Omega = \int r_t(\theta, \phi) Y_{\ell}^m(\theta, \phi) \cos \phi d\phi d\theta. \quad (3)$$

The $\cos \phi$ term is the spherical area element and corrects the latitude-dependent oversampling of ERP images. Hence, $\mathbf{b}^{(t)}$ is the SH encoding of the current observation shown in Fig. 3.

Propagated prior. Before fusing the new observation, the previous posterior belief must be aligned with the new orientation. Because the belief is maintained in the viewer-centric frame, it must rotate together with the agent. For an egocentric rotation $R_t \in SO(3)$, the previous posterior coefficients $\mathbf{c}^{(t-1)}$ are propagated into the current frame to produce the prior coefficients $\tilde{\mathbf{c}}^{(t)}$:

$$\tilde{c}_{\ell m}^{(t)} = \sum_{m'=-\ell}^{\ell} D_{mm'}^{\ell}(R_t) c_{\ell m'}^{(t-1)}. \quad (4)$$

For planar navigation, R_t reduces to the yaw change $\Delta\psi_t$. This corresponds to the lower branch in Fig. 3, where the previous posterior belief is rotated to obtain the propagated prior.

Belief Update. At the first timestep, the posterior belief is initialized directly from the first observation coefficients. For subsequent timesteps, the posterior belief is obtained by combining the propagated prior with the current observation coefficients:

$$c_{\ell m}^{(t)} = \tilde{c}_{\ell m}^{(t)} + b_{\ell m}^{(t)}. \quad (5)$$

This is the log-space Bayesian update: the propagated prior summarizes past information, while the observation coefficients contribute the current frame’s directional evidence. Importantly, $\mathbf{c}^{(t)}$ is

Figure 5: **Direction Estimation under Stationary and Mobile Operation.** Top: stationary robot with moving target, $(\cdots)$ is the target trajectory. Bottom: moving robot with stationary target. In each frame, $(\rightarrow)$ denotes the spherical directional prediction, $(\rightarrow)$ the ERP-based VLM baseline, and $(\square)$ the accumulated directional belief field. $\circ$ = Target, and $(\rightarrow)$ denotes the Ground Truth.

the posterior belief only for the current timestep t . After the agent takes an action and receives the next panorama I_{t+1} , this posterior is carried forward and serves as the previous posterior belief for the next update, i.e., it becomes the input state used to construct $\tilde{\mathbf{c}}^{(t+1)}$. In this way, each timestep forms a new observation term $\mathbf{b}^{(t)}$ from the current panorama, while the posterior from the preceding timestep provides the memory that links the recursion across time.

Direction decoding. After updating the belief, we recover a single direction estimate via the *spherical mean* of the belief field, i.e., the Fréchet mean on S^2 .

$$\hat{\omega}_t^* = \frac{\mathbf{m}_t}{\|\mathbf{m}_t\|}, \quad \mathbf{m}_t = \int_{S^2} f_t(\omega) \omega d\Omega \quad (6)$$

Since the degree-1 SH coefficients encode the mean direction analytically, $\mathbf{m}_t$ is computed directly in coefficient space without grid search or gradient ascent, degenerating to the MAP estimate under a unimodal belief. The resultant length $R_t = \|\mathbf{m}_t\| / \int_{S^2} f_t d\Omega \in [0, 1]$ provides a confidence measure analyzed in *Sec. 1.3 of Suppl. Mat.* Together, these steps define a recursive Bayesian filter on S^2 : the current panorama produces a directional log-likelihood observation, the SH coefficients store the running belief state, Wigner- D rotation propagates the previous posterior into the current frame, and spherical mean decoding returns the final egocentric target direction.

4 Experiments and Evaluation

4.1 Experimental Settings and Implementation Details

We evaluate EAGOR as a training-free, model-agnostic framework for embodied omnidirectional reasoning. Our evaluation is designed to validate two core claims: that SH-BF maintains geometrically consistent directional belief under egocentric motion, and that this geometric correctness translates to improved task performance across spatial tasks like navigation and active visual search without task-specific training. *Embodied Omni-directional Reasoning in Simulation* validates the geometric modeling of our framework in Habitat [41, 42]: (a) **Waypoint Following** tests directional belief consistency under egocentric motion and seam crossings, while (b) **Map-Free Navigation** evaluates whether geometric correctness translates to reliable closed-loop navigation without a map. (c) **Active Visual Search** evaluates EAGOR on *object search under partial panoramic observation* in H*-Bench HOS [30] and *multi-object egocentric spatial reasoning* in OSR-Bench [21]. Although these benchmarks were originally designed for supervised direction regression, EAGOR adapts to them without any task-specific training by interpreting each partial observation as a directional likelihood on the sphere. For *Real-World Validation*, we deploy EAGOR on a Unitree-Go2 equipped

Figure 6: **Embodied omni-directional reasoning in Habitat-Sim:** (a) *Waypoint Following* (b) *Map-Free Navigation*.

consistent directional belief under egocentric motion, and that this geometric correctness translates to improved task performance across spatial tasks like navigation and active visual search without task-specific training. *Embodied Omni-directional Reasoning in Simulation* validates the geometric modeling of our framework in Habitat [41, 42]: (a) **Waypoint Following** tests directional belief consistency under egocentric motion and seam crossings, while (b) **Map-Free Navigation** evaluates whether geometric correctness translates to reliable closed-loop navigation without a map. (c) **Active Visual Search** evaluates EAGOR on *object search under partial panoramic observation* in H*-Bench HOS [30] and *multi-object egocentric spatial reasoning* in OSR-Bench [21]. Although these benchmarks were originally designed for supervised direction regression, EAGOR adapts to them without any task-specific training by interpreting each partial observation as a directional likelihood on the sphere. For *Real-World Validation*, we deploy EAGOR on a Unitree-Go2 equipped

with an Insta360-X3 camera for **(d) Target Direction Estimation** under stationary and mobile operation, verifying that geometric correctness transfers to physical deployment under real sensor noise. At each timestep, the agent moves a fixed step along $\hat{\omega}_t^*$; the resulting parallax remains within single-frame observation noise, avoiding explicit translational compensation.

Baselines and Implementation Details. For HOS, OSR-Bench, and real-world evaluation, we compare *Qwen2.5+EAGOR* and *Gemma-3+EAGOR* against fine-tuned and zero-shot VLM baselines. For navigation-based experiments, we compare EAGOR against three ERP-space baselines: *Centroid*, *Centroid-Circ*, and *Grid*. All experiments, including the baselines, are conducted under same setting on a system with $4\times$ NVIDIA RTX 5090 GPUs, each with 32GB of VRAM.

Additional experimental and baseline details are provided in *Suppl. Mat. Sec. 2*.

4.2 Results and Discussion

We organize our evaluation around three experimental questions –

EQ-1: Can EAGOR adapt and improve end-to-end active visual search by converting VLM observations into a continuous directional belief across different VLM backbones ?

EQ-2: Does EAGOR provide geometrically equivariant directional reasoning under egocentric motion, seam crossings, and map-free navigation in simulated 360° environments?

EQ-3: Can EAGOR maintain consistent omni-directional reasoning in real-world settings ?

Active Visual Search. Table 1 presents the quantitative results on H*-Bench Humanoid Object Search (HOS) and OSR-Bench. For HOS, we evaluate EAGOR across frozen VLM backbones ranging from 3B to 12B parameters under a fully zero-shot setting. Across all backbones, EAGOR consistently improves target-direction estimation, achieving roughly $1.7\times$ – $2.2\times$ gains over the corresponding standalone models. Notably, *Qwen2.5-VL-7B* with *EAGOR* surpasses the larger standalone *Gemma-3-12B*, showing that explicit spherical belief reasoning can outweigh increased backbone capacity. We further evaluate *EAGOR* on 2,000+ OSR-Bench on multi-target relative-direction queries. As shown in Table 1, *EAGOR+Qwen2.5-VL-7B* achieves **25.2%**, outperforming its canonical backbone (**16.8%**), the $10\times$ larger *Qwen2.5-VL-72B* (**18.1%**). EAGOR is also efficient, converging in $1.4\times$ fewer views than the baseline, with accuracy improving monotonically from 8.5% to 40.1% across turns. Refer to *Suppl. Mat. Sec. 3* for qualitative results and additional analyses.

[A-1] By transforming VLM observations into a persistent directional belief, EAGOR consistently improves embodied omni-directional reasoning across frozen VLM backbones, enabling smaller models to outperform substantially larger ones without task-specific training.

Waypoint Following. Table 2 presents the mean angular error across (MAE) four sequential trajectory segments (*L1–L4*), with increasingly challenging turns between segments, together with robustness under occlusion, seam crossings, and temporal inconsistency. The raw VLM centroid degrades substantially under rotation and seam crossings, while Cent-Circ only partially alleviates wrap-around errors. Grid introduces temporal accumulation, but remains unstable under rotation and occlusion. In contrast, EAGOR achieves the lowest error across all segments and robustness conditions, while reducing temporal inconsistency from 7.3° – 19.2° /step to 2.6° /step. Fig. 6a shows that baseline errors spike after turns and near seam boundaries, while EAGOR maintains overall low angular error (-34.4°) while handling seam crossings resulting in more accurate path following.

Map-Free Navigation. Table 3 evaluates closed-loop navigation with *Qwen2.5-VL-7B* from near-opposite initial headings, where the agent executes the predicted direction at each step. EAGOR achieves the best performance across all metrics, with the highest success rate and path efficiency

Table 1: **Results for Active Visual Search** on HOS and OSR-Bench. Best accuracy in **bold** and second-best underlined.

Method	Params	Humanoid Object Search				OSR-Bench
		Overall	Easy	Medium	Hard

+ EAGOR	7B	40.10	<u>54.20</u>	39.40	34.60	25.2

Table 2: **Waypoint Following.** Mean angular error (MAE, $^{\circ}$, $\downarrow$) over four trajectory segments ($L1-L4$). Δ denotes trajectory degradation; *Occ* and *Seam* report MAE under occlusion and seam crossing error ($^{\circ}$, $\downarrow$); *TC* measures temporal inconsistency ($^{\circ}$ /step, $\downarrow$).

Method	L1	L2	L3	L4	Δ	Occ	Seam	TC
Centroid	25.5	49.4	90.9	66.7	+40.3	31.1	59.1	11.6
Cent-Circ	25.5	49.3	66.3	72.8	+46.4	31.1	51.0	7.3
Grid	23.2	138.9	37.3	75.9	+52.3	135.2	42.4	19.2
EAGOR	21.1	31.1	40.9	47.1	+25.4	15.5	22.9	2.6

Table 3: **Map-Free Navigation.** Closed-loop navigation from near-opposite headings ($|\theta| \approx 180^{\circ}$). Metrics include success (SR), path efficiency (SPL), steps, MAE, and seam-crossing success.

Method	SR $\uparrow$	SPL $\uparrow$	Steps $\downarrow$	MAE $\downarrow$	Seam $\uparrow$
Centroid	82	54.4	61.0	45.9	19.6
Cent-Circ	62	41.5	77.8	46.5	33.5
Grid	82	41.4	63.6	54.2	15.8
EAGOR	94	56.8	50.2	33.8	70.6

(94% SR and 56.8 SPL), the fewest steps (50.2), and the lowest angular error (33.8°). Although Cent-Circ improves seam handling over Centroid, its lower success rate indicates that per-frame wrap-around correction is insufficient for reliable control. Similarly, Grid matches Centroid in success rate but produces less efficient trajectories, showing that temporal accumulation alone does not ensure geometrically consistent actions. EAGOR further achieves substantially stronger seam robustness (70.6). As illustrated in Fig. 4 and Fig. 6b, EAGOR enables efficient and successful closed-loop navigation. Additional results are provided in the *Suppl. Mat. Sec. 3*.

[A-2] EAGOR, therefore, provides geometrically consistent directional reasoning in simulated 360° environments by maintaining a persistent spherical belief that remains stable under ego-centric motion and seam crossings, and translates into reliable map-free navigation.

Target Direction Estimation under Stationary and Mobile Operation. Fig. 5 qualitatively evaluates directional estimation when the robot is stationary and while it moves to follow a target. Across both settings, EAGOR maintains a coherent target direction despite real sensor noise, viewpoint changes, ego-motion, and temporary target disappearance. Additional results in *Suppl. Mat. Sec. 3*.

[A-3] EAGOR maintains consistent omni-directional reasoning in real-world indoor environments, preserving a coherent target-direction belief under both stationary and mobile robotic operation despite sensor noise, viewpoint changes, and ego-motion.

4.3 Ablation on SH Bandlimit and Runtime Analysis

The SH bandlimit L balances angular precision and side-lobe ringing. As shown in Fig. 7, larger L yields sharper localization but stronger oscillations at wider angular separations. We use $L = 7$, which provides $\approx 25^{\circ}$ angular resolution while avoiding excessive Gibbs ringing.

Running Time. EAGOR requires $0.6\times$ more inference time than the baseline (~ 1.6 vs. ~ 1.0 s with Qwen2.5-VL-7B), with almost *no extra* GPU memory. This is marginal for a training-free approach and can be further reduced via optimizations [46, 47].

Figure 7: **Effect of SH bandlimit.**

5 Conclusion, Limitations, and Future Work

Conclusion. We introduced **EAGOR**, a training-free framework for embodied omni-directional reasoning that formulates dynamic target localization as recursive belief estimation on the sphere. By maintaining a continuous egocentric directional belief and propagating it consistently under motion, EAGOR enables geometry-aware reasoning beyond frame-wise panoramic localization. Experiments in simulation and on a real-world legged robot demonstrate the importance of spherical belief representations for robust embodied omni-directional perception.

Limitations and Future Work. EAGOR uses VLM observations as directional likelihoods and is therefore sensitive to semantic ambiguity and perception errors. As shown in Tab. 4, its main failure modes arise from rare targets, multi-instance confusion, and false detections. Nevertheless, its performance on multi-instance cases indicates that cross-view belief accumulation partially mitigates ambiguous observations. Future work will incorporate grounded detection for multi-instance disambiguation and translation-aware, multi-sensor formulations for parallax-aware reasoning. We will explore bio-inspired perception for improved efficiency [48, 49]. Project will be made public.

Table 4: **Failure mode analysis on HOS dataset (Qwen2.5-VL-7B).**

Failure Mode	Episodes	Success Rate (%)
OCR / fine-grained text	18.5	13.2
Rare target	16.9	3.6
Multi-instance confusion	12.5	33.3
VLM false detection	11.9	13.6
<i>Overall</i>	<i>59.9</i>	<i>40.1</i>
