

Absorption-Feature-Guided Distance-Decoupled Estimation and Band Selection for LWIR Hyperspectral Passive Ranging

Shuo Liu, Chen Fan, Zhihe Chen, Xiaolin Huang, and Lilian Zhang

Abstract—In long-wave infrared (LWIR) hyperspectral observations, atmospheric absorption varies with propagation distance and introduces distance-related spectral variations into the observed target radiance, providing a physical basis for long-range passive ranging. However, in natural scenes, distance-related atmospheric absorption signatures are nonlinearly coupled with target temperature, material emissivity, and path radiance, making distance inversion from the observed radiance ill posed. Existing methods typically use full-band measurements and pixel-wise gradient-based joint optimization to estimate distance, temperature, and emissivity, which incurs high computational cost and does not explicitly exploit sharp atmospheric absorption structures for efficient distance estimation. To address these issues, this paper proposes an Absorption-Guided Distance-Decoupled Estimation and Refinement (ADER) framework for LWIR hyperspectral passive ranging. ADER represents material emissivity with B-spline control points under a smoothness prior, suppressing overfitting to sharp atmospheric absorption structures and facilitating distance-decoupled estimation from the observed radiance. Using ozone-absorption cues to identify reflected downwelling radiance, ADER classifies pixels into emission-dominant and reflection-dominant groups. For emission-dominant pixels, ADER compensates path radiance and transmittance to obtain an absorption residual, and then estimates distance through one-dimensional residual minimization. For reflection-dominant pixels, ADER refines the initial distance obtained from distance-decoupled estimation by introducing downwelling-radiance compensation based on the complete radiative model. To reduce spectral redundancy and enable efficient few-band ranging, this paper further proposes a greedy band selection strategy based on multi-scene effective Fisher information for the distance parameter. Experiments on real scenes demonstrate that ADER recovers spatial distance structures consistent with the LiDAR reference under both full-band and 20-band settings. By avoiding unified joint optimization over all pixels, ADER improves ranging accuracy in the evaluated regions and achieves approximately two orders of magnitude speedup over the public full-band hyperspectral ranging method.

Index Terms—Atmospheric absorption, distance-decoupled estimation, band selection, LWIR hyperspectral imaging, downwelling radiance.

1 INTRODUCTION

DISTANCE estimation is fundamental to autonomous driving, scene understanding, and topographical surveying [1]–[3]. Existing ranging methods usually rely on either active sensors or visible-spectrum geometric cues. Active sensors, such as LiDAR, provide accurate range measurements, but are limited by power consumption, eye safety, and covertness [4]. Passive geometric methods, including stereo vision and monocular depth estimation, are sensitive to illumination changes and texture deficiency, making reliable depth recovery difficult in nighttime, dense fog, and texture-scarce scenes [5]–[9]. These limitations motivate passive ranging methods that do not rely on active illumination or visible-spectrum geometric texture [10].

LWIR hyperspectral imaging provides a physics-based route for passive ranging beyond geometry-based vision [11], [12]. In the LWIR band, the thermal emission peak of natural targets at ambient temperature lies within the operating spectral range, enabling target radiance observation under low-light or no-illumination conditions [13].

Meanwhile, hyperspectral imaging provides fine spectral resolution and can capture the influence of absorption features from gases such as water vapor, carbon dioxide, and ozone on target radiance [14], [15]. According to the Beer-Lambert law, atmospheric absorption varies with propagation distance and leaves distance-dependent atmospheric absorption signatures in the observed spectrum, which provides the physical basis for LWIR hyperspectral passive ranging [16].

However, converting this absorption mechanism into pixel-wise distance estimation remains challenging. The observed radiance is a mixture of target emission, atmospheric path radiance, and reflected radiance [14], [15], [17]. Therefore, target distance d , target temperature T , and wavelength-dependent emissivity $\varepsilon(\lambda)$ are nonlinearly coupled in the observed spectrum. Different combinations of these physical variables may produce similar spectral responses, making distance recovery an underdetermined and ill-conditioned inverse problem [16], [18]. Prior work has shown that absorption features can provide physical cues for depth or distance recovery [19], [20]. For LWIR hyperspectral observations, recent work has demonstrated that atmospheric absorption signatures can be used for passive ranging in natural scenes by jointly estimating distance, temperature, and per-band emissivity from full-band mea-

Fig. 1: Motivation, pipeline, and representative ranging results of the proposed ADER framework. The left part shows selected pixels and their corresponding radiance spectra from a real LWIR hyperspectral observation, illustrating the coupling among distance, temperature, and material emissivity in the observed radiance. The middle part summarizes the main ADER pipeline, where either full-band spectra or selected 20-band spectra are used as input for B-spline emissivity modeling, ozone-feature-based pixel classification, and pixel-wise ranging. Emission-dominant pixels, such as P1 and P2, are processed by distance-decoupled estimation, whereas reflection-dominant pixels, such as P3, are processed by distance refinement with downwelling-radiance compensation. The right part presents representative ADER full-band and ADER 20-band ranging results.

surements [12]. However, existing LWIR hyperspectral ranging methods mainly treat atmospheric absorption as part of the inversion model. The per-band emissivity representation introduces excessive degrees of freedom, making it difficult to exploit the difference between sharp atmospheric absorption structures and smooth material emissivity to explicitly decouple distance from the observed radiance. As a result, their computational efficiency remains limited. Moreover, pixels in natural scenes may have different dominant radiative mechanisms. For most high-emissivity targets, the reflected radiance can be neglected and the observed radiance can be simplified to target emission and path radiance [12]. In contrast, for reflection-dominant regions such as reflective boards and sky boundaries, neglecting reflected downwelling radiance can cause distance overestimation [21]. Using a unified model for all pixels therefore makes it difficult to balance model completeness and computational efficiency. This motivates pixel classification according to different dominant radiative mechanisms and the design of corresponding distance estimation strategies. In addition, although full-band hyperspectral observations provide richer spectral information, they also introduce substantial spectral redundancy and unnecessary data acquisition and computational burden [22]–[24]. Most existing band selection methods are designed for classification, target recognition, or other remote sensing tasks, rather than for passive ranging. Meanwhile, very-low-band configurations, such as bispectral or quadrspectral ranging, may sacrifice ranging accuracy in complex real scenes [21]. Therefore, LWIR hyperspectral passive ranging requires a more task-specific band selection strategy that reduces spectral redundancy while preserving ranging accuracy.

These limitations indicate that LWIR hyperspectral passive ranging should not rely on full-band numerical optimization alone. Instead, distance information should be separated from the observed radiance by explicitly exploiting atmospheric absorption structures and the smoothness of material emissivity. To this end, we propose an Absorption-Guided Distance-Decoupled Estimation and Refinement (ADER) framework for LWIR hyperspectral passive ranging. ADER represents material emissivity with B-spline control points under a smoothness prior. This low-dimensional representation reduces emissivity unknowns and suppresses the fitting of sharp atmospheric absorption structures by the emissivity estimate. ADER then uses ozone-absorption cues to identify reflected downwelling radiance and classifies scene pixels into emission-dominant and reflection-dominant groups. For emission-dominant pixels, ADER compensates path radiance and transmittance, extracts the absorption residual, and estimates distance by a one-dimensional residual minimization. For reflection-dominant pixels, ADER incorporates the complete radiative model with downwelling-radiance compensation to refine the distance initialized by the distance-decoupled estimate. Furthermore, we design a greedy band selection strategy based on multi-scene effective Fisher information for the distance parameter to reduce spectral redundancy. Experiments show that ADER recovers LiDAR-consistent spatial ranging results under both full-band and 20-band settings. Meanwhile, it achieves higher ranging accuracy and efficiency than prior methods. Fig. 1 gives an overview of the motivation, processing pipeline, and representative results of ADER.

The main contributions of this paper are summarized as

follows:

- To limit the overfitting of emissivity to atmospheric absorption structures, we establish a B-spline emissivity control-point radiative model under a smoothness prior. This model reduces the number of emissivity unknowns and facilitates distance-decoupled estimation from the observed radiance.
- To avoid high-dimensional optimization over all image pixels and improve computational efficiency, we propose a pixel-classification-based distance estimation and refinement strategy. Using downwelling-radiance cues, ADER classifies pixels into emission-dominant and reflection-dominant groups. For emission-dominant pixels, distance estimation is formulated as a one-dimensional search problem based on absorption residual minimization. For reflection-dominant pixels, the complete radiative model with downwelling-radiance compensation is used for distance refinement. Compared with the evaluated public full-band hyperspectral ranging baseline, this design achieves approximately two orders of magnitude speedup.
- To reduce spectral redundancy and enable efficient few-band ranging, we propose a greedy band selection strategy based on multi-scene effective Fisher information for the distance parameter. By maximizing the incremental information gain, the proposed strategy selects distance-sensitive bands with complementary information. Experiments show that approximately 20 selected bands maintain ranging results close to the 256-band setting, reducing the number of used bands by about one order of magnitude.

The remainder of this paper is organized as follows. Section 2 reviews related work. Section 3 introduces the radiative model, B-spline emissivity representation, and pixel classification strategy based on downwelling-radiance cues. Section 4 analyzes distance information in atmospheric absorption structures and presents the distance-decoupled estimation and reflection-compensated refinement of ADER. Section 5 describes the band selection strategy for the ranging task. Section 6 evaluates ADER on real scenes. Finally, Section 7 concludes this paper.

2 RELATED WORK

2.1 Absorption-Based Passive Ranging

Absorption-based passive ranging exploits the wavelength-dependent attenuation of target radiance during atmospheric propagation. Because gas absorption varies with wavelength and propagation distance, the measured radiance spectrum contains implicit range information, which forms the physical basis of passive absorption-based ranging.

Early studies mainly focused on high-temperature targets, such as missile plumes, rocket exhausts, jet engines, and thermal lamps. Leonpacher and Hawks investigated passive infrared ranging using CO₂ or O₂ absorption spectra [25], [26]. Subsequent works further developed few-band passive ranging systems based on O₂ absorption, bandpass filtering, or imaging instruments [27]–[30]. These methods usually estimate atmospheric transmittance from

the radiance ratio between an absorption band and a nearby transparent band, and then map the estimated transmittance to target distance using a precomputed transmittance–range relation.

However, this high-temperature-target assumption does not readily extend to natural scenes. Long-term observations of ground–air temperature variations provide background evidence for the weak temperature contrast often encountered in natural environments [31]. Targets such as grass and rocks may have temperatures close to the surrounding air, making the distance-dependent absorption modulation weak and difficult to estimate. Recent advances in LWIR multispectral and hyperspectral imaging have extended absorption-based ranging to low-temperature-contrast scenes. Nagase *et al.* demonstrated the feasibility of passive ranging in real scenes by modeling the attenuation of LWIR thermal radiation through air [11]. Building on this line of work, Kushida *et al.* introduced an affine-transform representation for multispectral LWIR depth sensing to reduce calibration cost, while enabling closed-form estimation of object distance and temperature [20]. Dorken Gallastegi *et al.* analyzed the performance limits of LWIR hyperspectral absorption-based ranging from theoretical and simulation perspectives [16]. They further proposed a systematic LWIR hyperspectral passive ranging method, including bispectral and hyperspectral formulations, and estimated distance in real natural scenes within the 8–13.2 μm band while jointly estimating temperature and emissivity [12]. In the hyperspectral formulation, full-band joint optimization and emissivity smoothness regularization were used to improve inversion stability. That work also showed that external atmospheric priors are beneficial for distance estimation, and that more spectral observations help reduce range uncertainty caused by temperature contrast and measurement noise. More recently, to address reflected downwelling radiance, Gallastegi *et al.* represented the reflected component using downwelling radiance spectra precomputed at different zenith angles, thereby mitigating range overestimation in reflection-dominant regions rather than simply discarding these pixels [21].

Overall, absorption-based ranging has evolved from high-temperature targets to ambient-temperature objects in natural scenes, and from few-band ratio methods to LWIR multispectral and hyperspectral joint inversion. Recent studies have also incorporated downwelling-radiance characteristics to improve ranging accuracy. However, many existing hyperspectral ranging methods still rely mainly on full-band joint inversion and do not sufficiently exploit absorption structures to simplify distance estimation in real scenes.

2.2 Atmospheric Compensation and Thermal Infrared Hyperspectral Inversion

LWIR hyperspectral remote sensing has long been used for material classification, target detection, and physical parameter retrieval. In conventional remote sensing tasks, atmospheric absorption is usually regarded as an unwanted disturbance. Atmospheric compensation therefore aims to estimate or correct atmospheric transmittance, path radiance, and downwelling radiance from sensor-observed radiance, so that surface-leaving radiance can be recovered

for subsequent tasks [13]–[15]. Typical methods estimate atmospheric effects using radiative transfer models, precomputed lookup tables, or in-scene information [17], [32], [33]. Different from absorption-based ranging, these methods usually assume that targets in the scene share an approximately common atmospheric transmittance function and aim to remove atmospheric absorption. In absorption-based ranging, however, transmittance varies with target distance, so the absorption structure should be preserved and used as the source of range information.

After atmospheric compensation, thermal infrared hyperspectral inversion usually further estimates physical variables such as temperature and emissivity. Temperature–emissivity separation (TES) is a typical underdetermined problem and requires additional physical priors. Existing studies have addressed this problem using ASTER-TES [34], linear emissivity constraints [35], low-dimensional wavelet representations [36], or joint estimation of atmospheric transmittance, temperature, and emissivity [18], [37]. For ground-based thermal infrared hyperspectral data, HADAR and its follow-up works, including TAG/SLOT and HAIR, further show that decomposing observed radiance into physical variables such as temperature, emissivity, and texture can improve passive physics-aware perception at night [10], [38], [39]. In particular, the B-spline emissivity representation used in TAG/SLOT suggests that low-dimensional smooth emissivity constraints are suitable for thermal infrared hyperspectral inversion [38].

Although these inversion tasks have different goals, they rely on a common physical fact: natural materials usually have relatively smooth emissivity spectra in the LWIR band. Existing hyperspectral ranging methods exploit this prior by imposing smoothness regularization on per-band emissivity to stabilize distance estimation [12]. Although this strategy is flexible, the per-band emissivity representation still introduces many unknowns and does not sufficiently resolve the coupling between distance and emissivity.

2.3 Hyperspectral Dimensionality Reduction

Hyperspectral images contain many adjacent and highly correlated spectral channels, which introduce spectral redundancy and computational burden. Therefore, dimensionality reduction is necessary for hyperspectral data analysis [22]. Existing dimensionality reduction methods are commonly divided into feature extraction and band selection.

Feature extraction methods map the original spectra into a new low-dimensional feature space and are useful for data compression and classification [23]. However, the transformed features no longer correspond to the original physical wavelengths, which weakens their physical interpretability [24]. Band selection directly selects a subset of bands from the original spectrum. It can reduce spectral redundancy while maintaining the performance of downstream tasks such as target recognition and spectral unmixing [40]–[42], and provides clearer physical interpretability [24]. However, most existing band selection methods are designed for general hyperspectral remote sensing tasks and rarely consider the observability of the distance parameter. Therefore, this paper develops a band selection strategy for

LWIR absorption-based ranging, aiming to reduce spectral redundancy while preserving ranging accuracy.

3 RADIATIVE MODEL AND PIXEL CLASSIFICATION

This section first formulates the radiative transfer model used by ADER. Based on the smoothness prior of material emissivity, the emissivity spectrum is represented using B-splines. The ozone absorption feature is further used as a cue for reflected downwelling radiance, enabling pixel classification into emission-dominant and reflection-dominant groups.

3.1 Standard Radiative Transfer Model

Fig. 2 illustrates the radiative model used in this paper. The standard radiative transfer model decomposes the radiance observed by the sensor into three components: target emission, reflected downwelling radiance, and path radiance [14], [15], [17]. The first two components originate from the target surface and are modulated by the wavelength-dependent atmospheric transmittance during propagation, while the third component originates from the thermal emission of air along the propagation path. In this paper, $B(\lambda; T)$ denotes the blackbody spectral radiance at wavelength λ and temperature T , and radiance is expressed in $W \cdot m^{-2} \cdot sr^{-1} \cdot \mu m^{-1}$.

When scattering is neglected and the atmosphere is assumed to be approximately homogeneous, the atmospheric transmittance can be described by the Beer–Lambert law. We use the unit-path transmittance $\tau_{1m}(\lambda)$ to describe distance-dependent attenuation [11], [12], [16], and the transmittance at distance d is written as

$$\tau(\lambda; d) = [\tau_{1m}(\lambda)]^d. \quad (1)$$

The complete observed radiance received by the sensor is modeled as

$$\begin{aligned} R_{\text{obs}}(\lambda) &= R_{\text{emit}}(\lambda) + R_{\text{ref}}(\lambda) + R_{\text{path}}(\lambda) \\ &= \tau(\lambda; d)\varepsilon(\lambda)B(\lambda; T) \\ &\quad + \tau(\lambda; d)(1 - \varepsilon(\lambda))L_{\downarrow}(\lambda) \\ &\quad + (1 - \tau(\lambda; d))B(\lambda; T_{\text{air}}). \end{aligned} \quad (2)$$

Here, R_{emit} , R_{ref} , and R_{path} denote the target-emission, reflected-downwelling-radiance, and path-radiance contributions received by the sensor, respectively. The variables $\varepsilon(\lambda)$, T , and T_{air} denote the target emissivity, target temperature, and air temperature, respectively. In this paper, the reflected radiance is modeled using downwelling radiance spectra at different zenith angles:

$$L_{\downarrow}(\lambda) = \sum_{n=1}^{N_s} v_n L_{\downarrow, n}(\lambda), \quad v_n \geq 0, \quad \sum_{n=1}^{N_s} v_n \leq 1. \quad (3)$$

where N_s is the number of zenith-angle components in the downwelling-radiance dictionary, $L_{\downarrow, n}(\lambda)$ denotes the MODTRAN-simulated downwelling radiance spectrum corresponding to the n -th zenith angle [43], and v_n is its weight. The weighted combination approximates the effective sky downwelling radiance incident on and reflected by the target surface [17], [21].

Fig. 2: Schematic illustration of the radiative transfer model used in ADER. The observed radiance is decomposed into target emission, reflected downwelling radiance, and path radiance. The sky downwelling radiance is represented by MODTRAN-simulated spectra at different zenith angles [43], [44], and the ozone absorption feature provides a cue for identifying reflection-dominant pixels with significant reflected downwelling-radiance contribution. The surface emissivity is represented using B-spline control points to reduce the number of unknowns and suppress the overfitting of atmospheric absorption structures.

In the LWIR band, many natural materials have high emissivity. For emission-dominant pixels, the reflected radiance is weak and can be approximately neglected. The model is then simplified to target emission and path radiance [45], [46]:

$$R_{\text{obs}}(\lambda) = \tau(\lambda; d) \varepsilon(\lambda) B(\lambda; T) + (1 - \tau(\lambda; d)) B(\lambda; T_{\text{air}}). \quad (4)$$

The atmospheric state of a scene can be specified using meteorological records such as air temperature, pressure, and humidity. Given these parameters, the unit-path atmospheric transmittance can be simulated and used as prior information for distance estimation. However, for a single emission-dominant pixel under the simplified model, K spectral observations still require estimating distance, temperature, and K per-band emissivity values, resulting in $K + 2$ unknowns. The problem is therefore underdetermined and the variables are coupled. Existing absorption-based ranging methods usually impose spectral smoothness constraints on emissivity and jointly estimate temperature, distance, and emissivity [12]. This motivates an improved emissivity representation that reduces the number of unknowns at the parameter level.

3.2 B-Spline Emissivity Representation

Emissivity spectra of natural materials in the thermal infrared band are usually smooth and continuous, with limited overall amplitude variation. By contrast, atmospheric transmittance is affected by gases such as water vapor, carbon dioxide, and ozone, and exhibits pronounced absorption peaks at specific wavelengths, leading to sharper absorption structures [45], [46]. This contrast makes a smoothness prior on emissivity physically reasonable.

Different from per-band emissivity modeling combined with spectral smoothness regularization, this paper uses B-spline functions to model the emissivity spectrum [35], [36], [38], [47]. B-splines have local support and continuous smoothness, and can represent the overall spectral curve with a small number of control points. Specifically, for the K operating bands of the sensor, the emissivity is represented as a linear combination of M B-spline basis functions:

$$\varepsilon(\lambda) = \sum_{m=1}^M u_m \phi_m(\lambda), \quad (5)$$

where $\phi_m(\lambda)$ denotes the m -th B-spline basis function, u_m is the corresponding control coefficient, and M is the number of control points. In general, $M \ll K$. Thus, the original K -dimensional per-band emissivity parameters are compressed into M -dimensional control coefficients. The B-spline basis functions $\phi_m(\lambda)$ are precomputed according to the operating wavelength range and sampled bands of the sensor.

During inversion, the basis functions are fixed, and only the control coefficients are estimated. Fig. 3 compares the B-spline fitting results for material emissivity and atmospheric absorption structures. To make the spectra consistent with the actual sensor observations, the high-resolution material emissivity spectra from the ECOSTRESS spectral library [45], [46] and the high-resolution atmospheric transmittance simulated by MODTRAN [43] are first integrated using the sensor instrumental spectral response function with a bandwidth of approximately 40 nm, and then re-sampled to 256 discrete bands. As shown in Fig. 3(b), for material emissivity spectra such as rock, vegetation, water, and manmade metal, 20–30 control points are sufficient

Fig. 3: Comparison of B-spline fitting for material emissivity and atmospheric absorption structures. (a) Representative material emissivity spectra from the ECOSTRESS spectral library [45], [46] and their fitting results, together with the atmospheric absorption structure simulated by MODTRAN [43] for comparison. (b) Mean fitting error under different numbers of control points. All high-resolution spectra are first integrated using the sensor instrumental spectral response function with a bandwidth of approximately 40 nm, and then resampled to discrete bands.

to keep the fitting error below 0.005. By contrast, under the same number of control points, the fitting error of atmospheric absorption structures is more than one order of magnitude larger. This indicates that B-splines are suitable for describing smooth material emissivity, but have difficulty fitting sharp atmospheric absorption structures, which is beneficial for the subsequent distance-decoupled estimation. The setting of the B-spline control-point number M and its sensitivity analysis are provided in Sec. B.1 of the supplementary material.

3.3 Downwelling-Radiance-Based Pixel Classification

Real scenes may contain regions strongly affected by reflected downwelling radiance, such as reflective boards and sky boundaries. For these reflection-dominant pixels, directly applying the simplified emission-dominant model

can lead to biased distance estimation. Existing studies have shown that the ozone absorption feature near $9.6 \mu\text{m}$ in the LWIR band can be used as a cue for identifying reflected downwelling radiance [21]. Since ozone is mainly distributed in the upper atmosphere and its absorption contribution along near-ground horizontal paths is weak, an ozone feature observed in the target spectrum is more likely to originate from sky downwelling radiance reflected by the target surface. This ozone feature therefore provides a physically grounded cue for identifying pixels strongly affected by reflected downwelling radiance.

Different from existing methods that apply a unified model to the whole image, ADER adopts a pixel classification strategy based on downwelling-radiance cues and classifies scene pixels into emission-dominant and reflection-dominant groups. Following the idea of detecting pixels with significant reflected downwelling radiance using ozone-related spectral features [21], we select two adjacent sampled bands near the ozone absorption feature and compute their local spectral difference as the ozone-feature score. For pixel p , the score is defined as

$$C_{O_3}(p) = |y_p(\lambda_a) - y_p(\lambda_b)|, \quad (6)$$

where $y_p(\lambda)$ denotes the observed radiance of pixel p at wavelength λ . In the current implementation, λ_a and λ_b are the two sampled bands closest to $9.52 \mu\text{m}$ and $9.57 \mu\text{m}$, respectively. The score is used to characterize the ozone-feature strength caused by reflected downwelling radiance.

The threshold is further normalized using the maximum ozone-feature score over the image:

$$\theta_{O_3} = \theta_0 \max_p C_{O_3}(p), \quad (7)$$

where θ_0 is a fixed normalization constant; its value is listed in the reproducibility details and kept unchanged in all experiments. According to the comparison between the ozone-feature score and the normalized threshold, the pixel class is determined by

$$p \in \begin{cases} \mathcal{P}_{\text{ref}}, & C_{O_3}(p) > \theta_{O_3}, \\ \mathcal{P}_{\text{emi}}, & \text{otherwise}, \end{cases} \quad (8)$$

where $\mathcal{P}_{\text{ref}}$ denotes the reflection-dominant pixel set and $\mathcal{P}_{\text{emi}}$ denotes the emission-dominant pixel set.

Fig. 4 shows the pixel classification result, where reflection-dominant pixels are marked in blue and the remaining pixels are treated as emission-dominant pixels. For emission-dominant pixels, the reflected downwelling radiance is weak, and the simplified radiative model without the reflected term is used by the low-dimensional distance-decoupled estimator. For reflection-dominant pixels, the complete radiative model with the reflected term is used for distance refinement. The band pair of $9.52 \mu\text{m}$ and $9.57 \mu\text{m}$ is not the only possible choice for pixel classification. Sec. B.2 of the supplementary material further analyzes adjacent-band choices and threshold perturbations, showing that the proposed pixel-classification mechanism is reasonably robust to these implementation choices.

Fig. 4: Pixel classification result based on downwelling-radiance cues. The blue regions denote reflection-dominant pixels, while the remaining regions denote emission-dominant pixels.

4 DISTANCE-DECOUPLED ESTIMATION AND REFLECTION-COMPENSATED REFINEMENT

We next analyze how atmospheric absorption structures encode distance information in the observed radiance. For emission-dominant pixels, we propose a decoupled distance estimation method based on absorption-residual minimization. For reflection-dominant pixels, we introduce reflection-compensated refinement to improve distance estimation under reflected downwelling radiance.

4.1 Basis for Distance Decoupling

In the emission-dominant radiative model in Eq. (4), distance information does not appear as an independent additive term in the observed radiance. Instead, it modulates the observed radiance through the atmospheric transmittance $\tau(\lambda; d)$. From the perspective of spectral structure, the B-spline emissivity is constrained in a low-dimensional smooth space, and the Planck function also varies smoothly with wavelength. Therefore, temperature and emissivity mainly determine the overall radiance magnitude and the slowly varying spectral background. By contrast, distance information is related to nonuniform atmospheric absorption and is more strongly reflected in local spectral variations within strong absorption bands. Thus, the observed radiance can be approximately interpreted as the combined effect of a smooth background and absorption-related structures, which provides the physical basis for distance decoupling.

Fig. 5 illustrates the different effects of target temperature T , emissivity $\varepsilon(\lambda)$, and distance d on the observed radiance. Using limestone emissivity from the ECOSTRESS spectral library, we simulate radiance spectra with the radiative model in Eq. (4). In these simulations, the atmospheric transmittance is generated by MODTRAN with an air temperature of 290 K, a pressure of 1010 mb, a water-vapor partial pressure of 12.12 mb, and a reference path length of 100 m [43]. The high-resolution transmittance is convolved with a Gaussian instrumental spectral response of approximately 40 nm and then resampled to the sensor bands. When the target temperature is fixed and the distance increases, the absorption structures in the simulated radiance become more pronounced, especially within the strong absorption bands. When the target distance is fixed and the temperature changes, the radiance mainly varies in overall magnitude. Moreover, a larger target-air temperature difference leads to more visible distance-related absorption structures, whereas a smaller temperature contrast weakens these structures and makes distance recovery more difficult.

Although the above analysis mainly applies to emission-dominant pixels, it reveals how distance information differs

(a) Distance variation

(b) Temperature variation

Fig. 5: Radiative simulation analysis using limestone emissivity from the ECOSTRESS spectral library [45], [46] and MODTRAN-simulated atmospheric transmittance under the atmospheric setting described in the text [43]. Strong absorption bands are highlighted by shaded background regions. (a) Simulated radiance curves at a target temperature of 283 K and target distances of 30 m, 70 m, and 120 m. The absorption structures become more pronounced as the distance increases. (b) Simulated radiance curves at a fixed distance of 70 m and target temperatures of 278 K, 283 K, and 291 K. Temperature mainly affects the overall radiance magnitude, while a smaller target-air temperature contrast weakens the absorption structures and makes distance recovery more difficult.

from temperature and emissivity in the observed radiance. This difference motivates the distance-decoupled estimator introduced in the following subsection.

4.2 Distance-Decoupled Estimation

For emission-dominant pixels, we rearrange Eq. (4) under a candidate distance d to compensate for path radiance and atmospheric attenuation:

$$\tilde{y}(\lambda; d) = \frac{y_{\text{obs}}(\lambda) - (1 - \tau(\lambda; d))B(\lambda; T_{\text{air}})}{\tau(\lambda; d)} \approx \varepsilon(\lambda)B(\lambda; T). \quad (9)$$

When the candidate distance is close to the true distance, the path-radiance term and the propagation attenuation are properly compensated. The resulting $\tilde{y}(\lambda; d)$ is then mainly determined by target self-emission and becomes closer to a smooth background governed by temperature and emissivity. This operation is similar in form to atmospheric compensation. However, conventional atmospheric compensation aims to suppress atmospheric absorption effects, whereas

the proposed method deliberately exploits the residual absorption structures as distance cues and searches for the distance that makes the compensated spectrum smoothest [17], [32], [33].

To further extract the distance-related component from the compensated radiance, this paper defines the residual projection operator as

$$P_{\text{res}} = I - \Phi\Phi^\dagger, \quad (10)$$

where Φ is the B-spline basis matrix sampled at the discrete sensor wavelengths, with $[\Phi]_{k,m} = \phi_m(\lambda_k)$, and $\Phi^\dagger$ denotes its Moore–Penrose pseudoinverse. The matrix $\Phi\Phi^\dagger$ projects a spectral vector onto the smooth B-spline subspace, and its orthogonal complement P_{res} extracts a nonsmooth residual that emphasizes distance-related absorption variations while also retaining noise and modeling errors. Let $\tilde{\mathbf{y}}(d) = [\tilde{y}(\lambda_1; d), \dots, \tilde{y}(\lambda_K; d)]^\top$ denote the compensated spectral vector. The compensated spectrum can then be decomposed as

$$\tilde{\mathbf{y}}(d) = \underbrace{P_{\text{res}}\tilde{\mathbf{y}}(d)}_{\text{absorption residual component}} + \underbrace{(I - P_{\text{res}})\tilde{\mathbf{y}}(d)}_{\text{smooth background component}}. \quad (11)$$

In this way, the compensated radiance is decomposed into an absorption residual component and a smooth background component. The first component is mainly related to distance, while the second component is mainly associated with temperature and emissivity. When the candidate distance is correct, the compensated spectrum should be smoother, and its absorption residual component should be smaller. Thus, distance estimation can be formulated as a one-dimensional search problem:

$$\hat{d} = \arg \min_{d \in \mathcal{D}} \|P_{\text{res}}\tilde{\mathbf{y}}(d)\|_2^2, \quad (12)$$

where $\mathcal{D}$ denotes the candidate distance range. This formulation avoids complex joint optimization over temperature, emissivity, and distance, and instead decouples distance estimation from the observed radiance. Fig. 6 illustrates this mechanism using a simulated rock spectrum with a true distance of 70 m and a target temperature of 287 K, which is 3 K lower than the air temperature. In the noise-free case, the distance-decoupled estimator obtains 70.2 m.

After distance estimation, the smooth compensated spectrum can be further used for temperature estimation and B-spline emissivity recovery. Since this paper focuses on distance estimation, the estimation procedure and result analysis for temperature and emissivity are provided in Sec. C of the supplementary material.

4.3 Theoretical Ranging Precision Analysis

To further evaluate how effectively the distance-decoupled estimator exploits the distance information in the observed spectrum, we analyze the theoretical ranging precision under the current model. Based on Eq. (4), the target temperature and emissivity are unknown in practical ranging and are coupled with distance in the observed radiance. Therefore, we treat the target temperature T and the B-spline emissivity control points as nuisance parameters, and define the parameter vector as

$$\boldsymbol{\theta} = [d, T, u_1, u_2, \dots, u_M]^\top. \quad (13)$$

(a) Compensated spectra

(b) Absorption residuals

Fig. 6: Illustration of the distance-decoupling mechanism using a simulated rock radiance spectrum. Strong absorption bands are highlighted by shaded background regions. (a) Observed radiance and compensated spectra under different candidate distances. When the candidate distance approaches the true distance of 70 m, the compensated radiance becomes smoother. (b) The upper panel shows the absorption residual curves under different candidate distances, while the lower panel shows the residual energy as a function of candidate distance. The residual energy reaches its minimum near the true distance.

Let $\varepsilon_k = [\Phi\mathbf{u}]_k$, and let $\mu_k(\boldsymbol{\theta})$ denote the noise-free radiance model at the k -th band:

$$\mu_k(\boldsymbol{\theta}) = \tau(\lambda_k; d)\varepsilon_k B(\lambda_k; T) + (1 - \tau(\lambda_k; d)) B(\lambda_k; T_{\text{air}}). \quad (14)$$

Assuming that each sampled wavelength is corrupted by independent identically distributed additive Gaussian noise, the observed radiance is written as

$$y_k = \mu_k(\boldsymbol{\theta}_0) + n_k, \quad n_k \sim \mathcal{N}(0, \sigma^2), \quad (15)$$

where $\boldsymbol{\theta}_0 = [d_0, T_0, u_{0,1}, \dots, u_{0,M}]^\top$ denotes the true parameter setting in the simulation. The Jacobian matrix with respect to all unknown parameters is written as

$$\begin{aligned} \nabla \boldsymbol{\mu} &= \begin{bmatrix} \frac{\partial \mu_1}{\partial d} & \frac{\partial \mu_1}{\partial T} & \frac{\partial \mu_1}{\partial u_1} & \dots & \frac{\partial \mu_1}{\partial u_M} \\ \frac{\partial \mu_2}{\partial d} & \frac{\partial \mu_2}{\partial T} & \frac{\partial \mu_2}{\partial u_1} & \dots & \frac{\partial \mu_2}{\partial u_M} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \frac{\partial \mu_K}{\partial d} & \frac{\partial \mu_K}{\partial T} & \frac{\partial \mu_K}{\partial u_1} & \dots & \frac{\partial \mu_K}{\partial u_M} \end{bmatrix} \\ &= [G_d \quad G_\xi]. \end{aligned} \quad (16)$$

where G_d is the derivative column corresponding to distance, and G_ξ is the derivative matrix corresponding to the nuisance parameters $\xi = [T, u_1, \dots, u_M]^\top$. The distance derivative in G_d is

$$\frac{\partial \mu_k}{\partial d} = \tau(\lambda_k; d) \ln \tau_{1m}(\lambda_k) [\varepsilon_k B(\lambda_k; T) - B(\lambda_k; T_{\text{air}})]. \quad (17)$$

Under the Gaussian noise assumption, the Fisher information matrix for the unknown parameters is given by [48]

$$\begin{aligned} F(\theta) &= \frac{1}{\sigma^2} \begin{bmatrix} G_d^\top G_d & G_d^\top G_\xi \\ G_\xi^\top G_d & G_\xi^\top G_\xi \end{bmatrix} \\ &= \begin{bmatrix} F_{dd} & F_{d\xi} \\ F_{\xi d} & F_{\xi\xi} \end{bmatrix}. \end{aligned} \quad (18)$$

In the presence of unknown temperature and emissivity, the information loss caused by nuisance parameters should be removed from the distance information. The effective Fisher information for the distance parameter is therefore given by the Schur complement:

$$J_d(\theta) = F_{dd} - F_{d\xi} F_{\xi\xi}^{-1} F_{\xi d}. \quad (19)$$

Here, F_{dd} represents the direct distance information, while $F_{d\xi}$, $F_{\xi d}$, and $F_{\xi\xi}$ describe the coupling between distance and the nuisance parameters. The Schur-complement term $F_{d\xi} F_{\xi\xi}^{-1} F_{\xi d}$ therefore quantifies the distance-information loss caused by the uncertainty of temperature and emissivity.

According to the Cramér–Rao lower bound, the corresponding nuisance-parameter-aware theoretical lower bound on the distance standard deviation is [48]

$$\sigma_{d,\text{CRLB}} = \frac{1}{\sqrt{J_d(\theta_0)}}. \quad (20)$$

This bound indicates that, for a fixed noise level, the theoretical distance precision is first determined by F_{dd} , which depends on the atmospheric absorption strength and the radiance contrast between target emission and path radiance. Meanwhile, the final effective distance information is also affected by the nuisance parameters, and the corresponding information loss is described by $F_{d\xi} F_{\xi\xi}^{-1} F_{\xi d}$.

To evaluate the gap between the algorithmic precision and the precision limit, we conduct 100 Monte Carlo trials on the simulated rock spectrum at a true distance of 70 m under different noise levels. The noise standard deviation is set according to the LWIR hyperspectral camera noise level reported in [10]. Table 1 compares the average estimated distance, the algorithmic standard deviation, and the CRLB. In the noise-free case, the estimated distance is consistent with that shown in Fig. 6(b). As the noise level increases, the algorithmic standard deviation remains close to the CRLB, with the Std/CRLB ratio below 1.04. This result indicates that, under the current simulation setting, the distance-decoupled estimator effectively exploits the available distance information in the observed radiance and achieves ranging precision close to the nuisance-parameter-aware theoretical limit.

TABLE 1: Monte Carlo ranging results at a true distance of 70 m.

Noise std.	ADER estimate	Std	CRLB	Std/CRLB
0.000	70.186 m	0.000 m	0.000 m	–
0.005	69.455 m	2.303 m	2.297 m	1.00
0.010	69.410 m	4.753 m	4.594 m	1.04

4.4 Reflection-Compensated Refinement

The distance-decoupled estimator relies on the weak-reflection assumption and is mainly applicable to emission-dominant pixels. For reflection-dominant pixels, neglecting downwelling radiance may cause the reflected component to be incorrectly interpreted as a longer propagation distance, leading to distance overestimation. Therefore, for the reflection-dominant pixel set $\mathcal{P}_{\text{ref}}$ identified by pixel classification based on downwelling-radiance cues, we further introduce the downwelling-radiance dictionary coefficient vector $\mathbf{v}$ into the complete radiative model for distance refinement.

According to the complete radiative model in Eq. (2), reflection-dominant pixels are refined by minimizing the discrepancy between the observed spectrum and the reconstructed spectrum. For each pixel in $\mathcal{P}_{\text{ref}}$, the refinement problem is formulated as

$$\begin{aligned} (d^*, T^*, \mathbf{u}^*, \mathbf{v}^*) &= \arg \min_{d, T, \mathbf{u}, \mathbf{v}} \sum_{k=1}^K (\hat{y}_k(d, T, \mathbf{u}, \mathbf{v}) - y_k)^2, \\ \text{subject to} \quad &0 \leq d \leq d_{\max}, \\ &T_{\min} \leq T \leq T_{\max}, \\ &0 \leq \varepsilon_k = [\Phi \mathbf{u}]_k \leq 1, \quad k = 1, \dots, K, \\ &v_n \geq 0, \quad n = 1, \dots, N_s, \\ &\sum_{n=1}^{N_s} v_n \leq 1. \end{aligned} \quad (21)$$

Here, d , T , $\mathbf{u}$, and $\mathbf{v} = [v_1, \dots, v_{N_s}]^\top$ denote the distance, temperature, B-spline emissivity control-point vector, and downwelling-radiance dictionary coefficient vector of the current pixel, respectively. The term $\varepsilon_k = [\Phi \mathbf{u}]_k$ denotes the B-spline-reconstructed emissivity at the k -th band, and v_n corresponds to the n -th zenith-angle downwelling-radiance atom. $\hat{y}_k(d, T, \mathbf{u}, \mathbf{v})$ is the reconstructed radiance at the k -th band obtained from the complete radiative model, and y_k is the corresponding observed radiance. In this paper, the Adam optimizer is used to solve Eq. (21), and the same refinement is independently applied to all pixels in $\mathcal{P}_{\text{ref}}$ [49].

Through this pixel-classification strategy, ADER applies one-dimensional distance-decoupled estimation to most emission-dominant pixels and introduces reflection-compensated refinement only for a small number of reflection-dominant pixels. This avoids discarding the distance estimates of reflection-dominant regions while reducing the computational cost of full-image joint optimization. The correction effect on real reflection-dominant regions is further evaluated in the experimental section.

5 GREEDY BAND SELECTION BASED ON MULTI-SCENE EFFECTIVE FISHER INFORMATION FOR DISTANCE

The above analysis shows that distance information is unevenly distributed across wavelengths and is mainly concentrated in strong absorption bands. Although full-band hyperspectral observations provide rich spectral information, they also introduce spectral redundancy and additional computational cost. To enable efficient few-band ranging, this section uses Fisher information to evaluate the distance-related contribution of different bands and proposes a greedy band selection strategy based on multi-scene effective Fisher information for distance. Unlike feature extraction methods in hyperspectral dimensionality reduction, band selection preserves the original wavelengths and therefore provides stronger physical interpretability [22], [24], [50]. To make the band selection analysis consistent with the experimental scene, this section uses the atmospheric transmittance prior corresponding to the ranging scene [21].

5.1 Fisher Information Analysis

Based on the analysis in Section 4.3, the Fisher information provided by the k -th band for a parameter is proportional to the squared first-order derivative of the observed radiance with respect to that parameter [48]. According to the noise-free radiance mean defined in Eq. (14), we define the single-band information scores for distance and temperature as

$$\begin{aligned} S_d(k; c) &= \frac{1}{\sigma_c^2} \left(\frac{\partial \mu_k(\theta^{(c)})}{\partial d} \right)^2, \\ S_T(k; c) &= \frac{1}{\sigma_c^2} \left(\frac{\partial \mu_k(\theta^{(c)})}{\partial T} \right)^2. \end{aligned} \quad (22)$$

where c denotes a reference scene, $\theta^{(c)} = [d^{(c)}, T^{(c)}, u_1^{(c)}, \dots, u_M^{(c)}]^\top$ denotes the corresponding parameter setting, and σ_c^2 denotes the noise variance. In our implementation, the same noise level is used for all reference scenes, so σ_c^2 only acts as a common scaling factor for the normalized scores. This score is intuitive: if the radiance of a band changes significantly with distance or temperature, that band provides stronger observable information for the corresponding parameter. Since the distance, target temperature, and emissivity conditions vary across real scenes, the information score computed under a single reference condition may be biased. Therefore, we compute the Fisher information under multiple representative reference scenes and take the average as the overall evaluation metric:

$$\bar{S}_d(k) = \frac{1}{|\mathcal{C}|} \sum_{c \in \mathcal{C}} S_d(k; c), \quad \bar{S}_T(k) = \frac{1}{|\mathcal{C}|} \sum_{c \in \mathcal{C}} S_T(k; c), \quad (23)$$

where $\mathcal{C}$ denotes the set of reference scenes, and $\bar{S}_d(k)$ and $\bar{S}_T(k)$ denote the average distance and temperature scores of the k -th band, respectively.

Fig. 7(b) compares the normalized effective Fisher information for distance under different band selection strategies. Taking the full-band information as one, the direct

(a) Single-band Fisher score

(b) Effective Fisher information for distance

Fig. 7: Fisher-information-based band selection analysis. (a) Single-band Fisher scores averaged over simulated rock spectra under different reference scenes. Each curve is independently normalized to compare the information distribution across wavelengths. The markers denote the bands selected by direct distance-score ranking and by the proposed greedy band selection strategy, respectively. (b) Effective Fisher information for the distance parameter under different band selection strategies, normalized by the full-band value.

distance-score ranking strategy gradually increases the effective distance information as more bands are selected. By contrast, the proposed greedy incremental strategy obtains a high level of effective distance information with approximately 20 selected bands. Although this information criterion does not directly correspond to the final ranging accuracy, it provides guidance for setting the number of selected bands in the experiments.

5.2 Greedy Incremental Band Selection

In this subsection, we design the band selection strategy. A straightforward idea is to select bands according to the single-band distance score. However, existing hyperspectral band selection studies have shown that independent ranking methods tend to ignore the correlation and redundancy among spectral bands [24], [50]. Therefore, we design a greedy incremental band selection strategy that starts from the accumulated Fisher information of the selected band set and progressively constructs the final band subset.

Following the Fisher information formulation in Eq. (18), we restrict the Jacobian to the selected band subset Ω and average the resulting Fisher information over multiple reference scenes. The multi-scene accumulated Fisher information matrix is defined as

$$\bar{F}(\Omega) = \frac{1}{|\mathcal{C}|} \sum_{c \in \mathcal{C}} \frac{1}{\sigma_c^2} \left(G_{\Omega}^{(c)} \right)^\top G_{\Omega}^{(c)}, \quad (24)$$

where $G_{\Omega}^{(c)}$ denotes the Jacobian matrix formed by the rows of $\nabla \mu$ in Eq. (16) that correspond to the selected bands in Ω , computed under the c -th reference scene. Different from the single-band score, $\bar{F}(\Omega)$ depends on the current band subset and describes the average accumulated constraint of this subset on the unknown parameters over multiple reference scenes.

Following the nuisance-parameter elimination in Eq. (19), we partition $\bar{F}(\Omega)$ according to the distance parameter and the nuisance parameters, and extract the information directly related to distance from the multi-scene accumulated Fisher information:

$$\bar{F}(\Omega) = \begin{bmatrix} \bar{F}_{dd}(\Omega) & \bar{F}_{d\xi}(\Omega) \\ \bar{F}_{\xi d}(\Omega) & \bar{F}_{\xi\xi}(\Omega) \end{bmatrix}. \quad (25)$$

The multi-scene effective Fisher information for distance is then defined as

$$\bar{J}_d(\Omega) = \bar{F}_{dd}(\Omega) - \bar{F}_{d\xi}(\Omega) (\bar{F}_{\xi\xi}(\Omega))^\dagger \bar{F}_{\xi d}(\Omega). \quad (26)$$

where $\xi = [T, u_1, \dots, u_M]^\top$ denotes the nuisance parameters, and the Schur-complement term represents the distance-information loss caused by the uncertainty of temperature and emissivity control points. The operator $(\cdot)^\dagger$ denotes the Moore–Penrose pseudoinverse, which is used to handle the possible rank deficiency or ill-conditioning of $\bar{F}_{\xi\xi}(\Omega)$ under few-band settings. The multi-scene effective Fisher information $\bar{J}_d(\Omega)$ is the core criterion used for band selection. Since it depends on the current selected band subset, it can reflect the redundancy among different bands. Directly enumerating the optimal subset from the full band set is computationally expensive, and similar measurement subset selection problems are commonly solved using approximate or greedy strategies [51], [52].

Given the current selected set Ω_t , the information gain of a candidate band $k \notin \Omega_t$ is defined as

$$\Delta \bar{J}_d(k | \Omega_t) = \bar{J}_d(\Omega_t \cup \{k\}) - \bar{J}_d(\Omega_t). \quad (27)$$

At each step, the band with the largest $\Delta \bar{J}_d(k | \Omega_t)$ is selected and added to the subset.

In addition, if the selected bands contain excessively large wavelength gaps, the emissivity fitting may become unstable and affect the ranging result. Thus, we introduce a wavelength-gap penalty and use the following selection criterion at each step:

$$k_{t+1} = \arg \max_{k \notin \Omega_t} [\Delta \bar{J}_d(k | \Omega_t) - \lambda_{\text{gap}} P_{\text{gap}}(k, \Omega_t)], \quad (28)$$

$$\Omega_{t+1} = \Omega_t \cup \{k_{t+1}\}, \quad (29)$$

where $P_{\text{gap}}(k, \Omega_t)$ denotes the wavelength-gap penalty, and λ_{gap} is the corresponding weight.

Fig. 7(b) compares the normalized distance information under the two selection strategies. With the full-band information normalized to one, the single-band distance-score strategy gradually increases as the number of selected bands grows. In contrast, the proposed greedy incremental strategy obtains a high level of distance information with about 20 bands. Although this information metric does not directly correspond to the final ranging accuracy, it provides a guideline for setting the number of selected bands in the experiments.

6 EXPERIMENTS

6.1 Experimental Data and Runtime Settings

We evaluate ADER on LWIR hyperspectral data from the DARPA Invisible Headlights dataset [53]. This dataset was collected for autonomous navigation in complex off-road environments and contains synchronized observations from multiple sensing modalities, including visible imaging, hyperspectral imaging, and LiDAR. The recorded scenes include natural environments such as forests, sandy terrain, and grassland. The LWIR hyperspectral data were acquired by a pushbroom LWIR hyperspectral imager equipped with a cooled HgCdTe detector. The two-dimensional sensor array spans the spectral dimension and the vertical spatial dimension, and the full data cube is obtained by scanning along the horizontal direction. This pushbroom acquisition mechanism may introduce horizontal stripe artifacts because of nonuniform pixel responses or abnormal spectral pixels. According to the sensor parameters reported in prior work, the spectrometer has a vertical field of view (VFOV) of 11.6° and a horizontal field of view (HFOV) of 57° . The focal length is 50 mm, and the f-number is $f/0.9$ [12]. For each pixel in the scene, the sensor acquires 256 spectral channels from $8.0 \mu\text{m}$ to $13.2 \mu\text{m}$, with a spectral resolution of approximately 40 nm. The typical sensor noise is approximately $0.01 \text{ W} \cdot \text{m}^{-2} \cdot \text{sr}^{-1} \cdot \mu\text{m}^{-1}$, corresponding to an SNR of about 1000:1 at $10 \mu\text{m}$ [10]. To reduce the influence of wavelength-calibration mismatch, we align the spectral bands of different scenes using atmospheric absorption features, making the measured spectra more consistent with the absorption structures used for ranging.

The dataset provides LiDAR distance measurements approximately registered with the image data, which are used as reference information for evaluating passive ranging results. We use Path5_Step1 as the main experimental scene for passive absorption-based ranging, following prior studies on this scene [12], [21]. This scene was collected at 19:41 local time on April 13, 2021, under low-illumination and weak-temperature-contrast conditions. The scene mainly consists of rolling grassy terrain, and also contains foreground trees, distant forest regions, and several checkerboard calibration targets with strong reflective properties. This scene contains both emission-dominant and reflection-dominant regions, making it suitable for evaluating ADER under weak temperature contrast and for analyzing pixel classification, reflection-compensated refinement, and band selection.

For the atmospheric priors, we use the atmospheric coefficients and LiDAR reference data released by prior work for this scene [21]. We further assume that the atmospheric state is approximately uniform within the scene, and use the same unit-path transmittance and air temperature for all pixels. The LiDAR distance map and the LWIR hyperspectral image are only approximately registered and do not have strict pixel-wise correspondence. Therefore, ranging performance is evaluated using local region statistics, distance profiles, and cross-scene visual comparisons rather than full-image pixel-wise error metrics. For patch-level quantitative evaluation, the median distance of the corresponding LiDAR patch is used as the reference distance

Fig. 9: Reflection-compensated refinement on reflective boards. (a) Decoupled-only result, where the reflective boards inside the dashed boxes are overestimated. (b) ADER full-band after refinement. (c) RGB reference. White crosses mark the centers of the two 8×8 evaluation patches.

result remains close to the full-band result. In this scene, the 20-band result shows weaker stripe artifacts, suggesting that the selected bands preserve the main distance-sensitive information while reducing the influence of redundant or unstable bands.

Following the region-based evaluation protocol used in prior work, three 20×40 representative patches are selected from emission-dominant regions, including grass, foreground trees, and background forest. The grass and foreground-tree patches have corresponding LiDAR reference regions, as marked in Fig. 8(c). For the background forest region, reliable LiDAR reference is unavailable, so we mainly evaluate the concentration and stability of the estimated distance distribution.

Prior work reported bispectral, quadspectral, and hyperspectral ranging results on the same scene, and also used local patches of the same size in the grass, foreground-tree, and background-forest regions for evaluation. However, the exact coordinates of the selected patches were not specified. Therefore, the reported values are used as literature reference values rather than strictly coordinate-aligned quantitative comparisons. For a same-region comparison, we run the released hyperspectral ranging code and evaluate the reproduced result on the same regions selected in this paper. The bispectral and quadspectral methods are computationally efficient, but their ranging accuracy is limited by the use of very few spectral bands. Thus, the reported hyperspectral result and the reproduced hyperspectral result are used as the main baseline comparisons.

Table 2 summarizes the distance mean, standard deviation, and runtime of different methods on the three selected regions. For the grass and foreground-tree regions, the mean distances obtained by ADER full-band are closer to the LiDAR median than those obtained by the compared hyperspectral baselines. In particular, the LiDAR median distance of the foreground-tree region is 57.48 m, while ADER full-band gives $56.11 \text{ m} \pm 10.08 \text{ m}$, showing a smaller bias than both the reported and reproduced hyperspectral results. Across the three selected regions, ADER full-band also gives the smallest standard deviation, indicating that

its distance estimates are more concentrated. The 20-band result remains close to the full-band result while using far fewer spectral bands, which further supports the effectiveness of the proposed band selection strategy.

In terms of computational efficiency, ADER full-band takes 77.2 s on this scene, while ADER 20-band takes 56.23 s. Under the same testing condition, the released hyperspectral ranging code takes 167.79 min. Therefore, the runtime of ADER full-band is reduced by approximately $130\times$, and the 20-band setting further improves the efficiency. Overall, ADER achieves minute-level scene ranging and produces estimates that are closer to the LiDAR median and more stable in the evaluated regions.

It should be noted that the foreground-tree region remains a challenging case. Although its mean distance is close to the LiDAR median, its standard deviation is still about 10 m. This dispersion is mainly related to the very low temperature contrast in this region, where the target-air temperature difference is below 1 K, as well as the complex internal structure of vegetation. For absorption-based ranging, when the target temperature approaches the air temperature, the observability of distance-related absorption structures decreases [16]. ADER therefore does not eliminate the uncertainty in this weak-temperature-contrast region, but reduces the bias and improves the local stability compared with prior results.

6.3 Reflection-Dominant Region Analysis

To further analyze distance estimation in reflection-dominant regions, this subsection conducts the evaluation from two aspects. First, we use the same regions as those defined in the released code of the prior method to evaluate the effect of reflection-compensated refinement on local ranging accuracy. Second, we examine larger reflective-board regions to assess the effect of the B-spline emissivity representation on spatial consistency.

Distance estimation for reflection-dominant pixels requires the complete radiative model that includes the reflected downwelling-radiance term. Specifically, we use

TABLE 3: Quantitative comparison on two 8×8 reflection-dominant patches.

Method	Front checkerboard	Rear checkerboard
Decoupled only	180.51 m $\pm$ 8.68 m	194.26 m $\pm$ 1.68 m
ADER full-band	30.41 m $\pm$ 6.97 m	44.87 m $\pm$ 2.36 m
HS (reported)	28.86 m $\pm$ 5.38 m	39.83 m $\pm$ 2.01 m
HS+TV (reported)	28.82 m $\pm$ 5.31 m	39.84 m $\pm$ 1.78 m
LiDAR median	31.01 m	46.51 m

the Adam optimizer together with an externally simulated downwelling-radiance dictionary to refine the detected reflection-dominant pixels, and jointly estimate the target temperature, distance, emissivity control coefficients, and downwelling-radiance coefficients. This refinement follows the downwelling-radiance dictionary modeling used in prior LWIR absorption-based ranging work [21].

Fig. 9 shows the correction effect of reflection-compensated refinement on the reflective-board regions. When only the decoupled estimation is used, the reflective-board regions suffer from clear distance overestimation. After reflection-compensated refinement, the overestimation is reduced and the distance distribution on each reflective board becomes more spatially uniform.

For comparability with prior work [21], we use two 8×8 pixel patches whose locations and sizes are exactly the same as the evaluation regions specified in the released code of the prior method. Table 3 reports the mean and standard deviation of the estimated distances in these two regions. Using only the decoupled estimate leads to severe distance overestimation in the reflection-dominant regions, indicating that the simplified model without reflection cannot explain the influence of downwelling radiance in these pixels. After reflection-compensated refinement is introduced, ADER full-band obtains distance estimates closer to the LiDAR median in the selected regions. By contrast, although HS+TV reduces the local standard deviation, its mean distance still shows evident underestimation. Overall, ADER full-band obtains smaller mean bias on both the front and rear checkerboards while maintaining reasonable local stability.

The above evaluation focuses on local accuracy. To assess spatial consistency across reflective boards, we further select larger rectangular regions covering different material subregions. Since prior work did not report statistics on these regions, we use the reproduced result as the baseline. We also construct ADER-per-band by replacing the B-spline emissivity representation with independent per-band emissivity variables while keeping the same refinement procedure.

Fig. 10 compares the HS baseline (reproduced), the ADER-per-band ablation variant, and ADER full-band on two reflective-board patches, together with the corresponding distance histograms. Both the HS baseline and ADER-per-band show clear within-board distance discontinuities, indicating unstable estimation in reflection-dominant regions. For ADER-per-band, the independent per-band emissivity variables introduce excessive spectral degrees of freedom, making distance inversion more susceptible to the coupled effects of temperature, emissivity, and downwelling radiance. In contrast, ADER full-band uses the B-

Fig. 10: Reflective-board ranging and histogram comparison. (a) Reproduced HS baseline. (b) ADER-per-band. (c) ADER full-band. (d),(e) Distance histograms of the front and rear checkerboards. Red boxes mark the patches used in Table 4.

TABLE 4: Distance distribution evaluation on selected reflection-dominant patches.

Method	Front checkerboard	Rear checkerboard
HS baseline (reproduced)	32.15 m $\pm$ 10.83 m	40.51 m $\pm$ 12.22 m
ADER-per-band	57.14 m $\pm$ 10.86 m	65.87 m $\pm$ 10.69 m
ADER full-band	36.04 m $\pm$ 6.12 m	47.74 m $\pm$ 4.70 m
LiDAR median	31.01 m	46.51 m

spline emissivity representation to constrain emissivity to a smooth low-dimensional space, thereby reducing this ambiguity and producing more spatially consistent distances and more concentrated histograms. Table 4 further confirms this improvement through the lower standard deviations on both reflective-board patches.

6.4 Reduced-Band Ranging and Cross-Scene Validation

Based on the greedy band selection strategy proposed in Section 5, we further evaluate reduced-band ranging on real scenes. The representative-region evaluation in Table 2 shows that ADER 20-band achieves ranging results close to ADER full-band using 256 bands, while substantially reducing the number of spectral bands. To further analyze the spatial consistency of ADER 20-band, this subsection first compares the distance variations of full-band and 20-band results along selected profile lines, and then evaluates the applicability of the selected bands on multiple real scenes.

Fig. 11(a) shows the ranging maps used for profile analysis, where the left image is the ADER full-band result and the right image is the ADER 20-band result. The red and blue dashed lines denote two selected vertical profiles that cover different scene structures. The red profile passes through near grass, reflective boards, and background forest, and is used to analyze distance variations under a mixture of emission-dominant and reflection-dominant pixels, as shown in Fig. 11(b). The blue profile mainly passes

Fig. 11: Profile comparison between ADER full-band and ADER 20-band results. (a) Profile locations. (b),(c) Red and blue profiles. The dashed curve denotes LiDAR, and the solid curves denote ADER results. Profile indices increase from bottom to top.

through grass, foreground trees, and background forest, and is used to evaluate ranging stability under weak temperature contrast and the separability between foreground trees and distant background forest, as shown in Fig. 11(c).

As shown in Fig. 11, ADER full-band and ADER 20-band both follow distance variation trends close to the LiDAR reference along the main regions of the two profiles. In particular, within the near-range region below 100 m, the results before and after band selection are largely consistent, indicating that the selected bands preserve the main distance-sensitive information. In challenging regions, including weak-temperature-contrast foreground trees, background forest, and reflective boards, ADER full-band produces smoother curves overall, while ADER 20-band still maintains a similar spatial trend without evident structural deviation. It should be noted that the LiDAR range map and the LWIR hyperspectral image are only approximately registered, so local differences between the profile curves may also be affected by registration mismatch. Overall, the profile analysis shows that ADER 20-band preserves spatial consistency close to the full-band result in the real scene, supporting the effectiveness of the proposed task-driven band selection strategy.

Fig. 12 shows cross-scene results on three additional IH scenes, with the MODTRAN atmospheric parameters marked below each scene. ADER 20-band preserves the main spatial structures of ADER full-band and shows trends

TABLE 5: Distance statistics on 20×20 selected patches from additional scenes. Bold mean values denote the ADER result closest to the LiDAR median in each scene.

Method	Path26_Step1	Path26_Step5	Path17_Step23
ADER full-band	22.20 m $\pm$ 4.25 m	12.68 m $\pm$ 3.95 m	19.65 m $\pm$ 4.75 m
ADER 20-band	25.22 m $\pm$ 4.92 m	10.58 m $\pm$ 5.48 m	18.70 m $\pm$ 4.50 m
LiDAR median	23.86 m	12.08 m	19.33 m

similar to the LiDAR reference. For quantitative evaluation, Table 5 reports the mean and standard deviation of ADER full-band and ADER 20-band on selected 20×20 patches, together with the LiDAR median. The 20-band result maintains an error level similar to the full-band result, indicating that the selected bands preserve the main distance information across scenes.

7 CONCLUSION

This paper presents ADER for LWIR hyperspectral passive ranging in natural scenes, where distance is nonlinearly coupled with temperature, material emissivity, path radiance, and reflected downwelling radiance. ADER uses atmospheric absorption structures to decouple distance estimation, rather than relying solely on full-band joint inversion. By representing emissivity with B-spline control points, classifying pixels according to downwelling-radiance cues, and selecting distance-sensitive bands using multi-scene effective Fisher information for the distance parameter, ADER reduces the dimensionality and spectral redundancy of the ranging problem while preserving the absorption information needed for distance estimation.

Experiments on real LWIR hyperspectral scenes show that ADER recovers spatial distance structures that are consistent with the approximately registered LiDAR reference. On the main scene, ADER provides more accurate local distance statistics than the public full-band hyperspectral ranging implementation and reduces the runtime from 167.79 min to 77.2 s, corresponding to an approximately $130\times$ speedup. The analysis of reflection-dominant regions further shows that reflection-compensated refinement reduces distance overestimation, while the B-spline emissivity representation improves the spatial consistency of the estimated distances on reflection-dominant regions. The reduced-band experiments indicate that ADER with 20 selected bands can maintain distance structures close to the full-band result in the evaluated scenes, supporting the use of task-driven band selection for LWIR hyperspectral passive ranging.

Despite these results, absorption-based ranging remains limited by weak distance observability when the target-air temperature contrast is extremely small or when atmospheric absorption attenuation is insufficient. The current implementation also depends on scene-level atmospheric priors and MODTRAN-simulated transmittance. Future work will focus on adaptive atmospheric parameter estimation, improved observability under weak temperature contrast, and system-level validation with calibrated LWIR hyperspectral sensors.

Fig. 12: Cross-scene ranging validation on additional IH dataset scenes. The rows show the visible reference image, approximately registered LiDAR reference, ADER full-band result, and ADER 20-band result, respectively. The red boxes denote the 20×20 patches used for Table 5. The MODTRAN atmospheric parameters are marked below each scene.

ACKNOWLEDGMENT

This work was supported in part by the National Natural Science Foundation of China under Grant 62103429, in part by the Innovation Research Foundation of National University of Defense Technology under Grant 24-ZZCX-JDZ-28, and in part by the Major Project of the Natural Science Foundation of Hunan Province under Grant 2021JC0004.
