Abstract

This paper proposes a public daily-frequency benchmark for post-GFC government-bond CIP deviations. Although CIP deviations are observed daily, the literature lacks a canonical benchmark for daily regressions comparable to standard factor models in asset pricing. Using G10 plus KRW currency–tenor panels, I show that three lagged public state variables—NFCI, the nominal broad U.S. dollar index, and the Treasury 10-year minus 2-year slope—deliver strong in-sample and leave-one-year-out performance. Cointegration, quarter-end, and aggregation-difference diagnostics suggest that the benchmark captures a persistent background component rather than short-maturity quarter-end spikes or spurious level correlation.

1 Introduction

Covered interest parity (CIP) is a central no-arbitrage relation in international finance. In frictionless markets, spot exchange rates, forward exchange rates, and interest-rate differentials should rule out covered currency arbitrage. Post-Global Financial Crisis data show that this relation does not fully close. Cross-currency bases and government-bond CIP deviations are persistent, and are linked to intermediary balance-sheet capacity, dollar funding pressure, regulation, hedging demand, and broader macrofinancial conditions (Baba et al., 2008; Baba and Packer, 2009a,b; Borio et al., 2016; Du et al., 2018a; Avdjiev et al., 2019; Cerutti et al., 2021; Rime et al., 2022).

This paper is motivated by a practical benchmarking gap. Daily CIP deviation panels are now available, but the empirical CIP literature has no standard daily-frequency public-data benchmark. This contrasts with empirical asset pricing, where standard factor models provide a common hurdle for new factors. Daily CIP regressions lack an analogous reference point. New funding, liquidity, regulatory, or intermediary-capital variables are therefore often judged against ad hoc specifications rather than against a transparent common benchmark.

This gap reflects the nature of the existing determinants literature. Many important CIP variables are balance-sheet, liquidity, regulatory, or institutional objects. They are economically central, but often lower-frequency, difficult to construct daily, or not easily reproducible from public sources. The dependent variable is daily, while many natural explanatory variables are not. I ask whether a small set of public state variables can summarize daily government-bond CIP deviations well enough to serve as a reproducible benchmark.

The benchmark uses three lagged macrofinancial variables: the Chicago Fed National Financial Conditions Index (NFCI), the nominal broad U.S. dollar index, and the Treasury 10-year minus 2-year yield slope. These variables summarize financial conditions, the global dollar cycle, and the U.S. yield-curve regime. I do not interpret them as new structural determinants of CIP deviations. They are public proxies for macrofinancial forces already emphasized in the literature. The contribution is to show that this compact specification provides a strong daily benchmark for the persistent component of post-GFC government-bond CIP deviations.

The scope is intentionally narrow. I study government-bond CIP deviations at maturities of three months and longer. This differs from the ultra-short quarter-end effects emphasized by Du et al. (2018a), where one-week or one-month contracts can move sharply when they begin to cross quarter-end reporting dates. The data used here begin at the three-month tenor. The paper therefore does not aim to explain the sharpest quarter-end spikes. It studies the background component of government-bond CIP deviations visible across daily

currency–tenor panels.

The empirical analysis uses the government-bond CIP deviation data of [Du et al. \(2025b\)](#). The sample runs from January 1, 2008 to June 30, 2025 and covers G10 currencies plus the Korean won. In each currency–tenor panel, I regress the CIP deviation on lagged NFCI, the lagged broad dollar index, and the lagged Treasury slope. The model uses no proprietary balance-sheet data, no currency-specific institutional variables, and no high-dimensional search over macrofinancial controls.

The results are large relative to the simplicity of the specification. In separate currency–tenor regressions, the within-panel in-sample R^2 is 0.637. The leave-one-year-out (LOYO) pooled out-of-sample R^2 is 0.499. These metrics remove currency–tenor mean differences and evaluate holdout observations against panel-specific estimation-sample means. The fit is therefore not driven mechanically by matching average levels across currencies or tenors.

The result also survives more restrictive specifications. When tenors are stacked within each currency and the three state-variable slopes are shared across tenors, the in-sample R^2 is 0.645 and the LOYO pooled R^2 is 0.607. Thus the fit is not simply a by-product of freely estimating every currency–tenor slope. A small public-data specification captures a substantial low-frequency component of post-GFC government-bond CIP deviations.

The coefficient patterns are economically interpretable. NFCI is positive in most panels and is the most consistently significant regressor, consistent with a limits-to-arbitrage view. The Treasury slope also tends to enter positively, suggesting that the U.S. yield-curve regime is linked to the persistent component of government-bond CIP deviations. The broad dollar coefficient is more heterogeneous, consistent with a global state variable whose effect depends on currency-specific funding and hedging pressures.

Several diagnostics clarify the scope of the benchmark. A short-tenor quarter-end dummy adds essentially no explanatory power, consistent with the three-month-and-longer maturity structure of the data. Cointegration and aggregation-difference diagnostics further suggest that the benchmark captures a persistent macrofinancial component rather than daily high-frequency noise or a purely spurious level relation. The specification should therefore be read as a benchmark for the background component of government-bond CIP deviations, not as a high-frequency arbitrage-execution model.

The contribution is a benchmark contribution. First, the paper identifies the absence of a canonical daily public-data benchmark for CIP deviations. Second, it proposes a compact three-variable specification that is easy to reproduce. Third, it shows that the benchmark delivers strong in-sample and out-of-sample performance in government-bond CIP panels. Fourth, it provides a simple empirical hurdle: richer explanations of background government-bond CIP deviations should demonstrate incremental power relative to this benchmark.

The remainder of the paper proceeds as follows. [Section 2](#) reviews the related literature. [Section 3](#) describes the data and methodology. [Section 4](#) presents the baseline results. [Section 5](#) reports the robustness diagnostics. [Section 6](#) discusses heterogeneity, regime dependence, and benchmark interpretation. [Section 7](#) concludes.

2 Literature Review

This paper relates to three strands of literature: classical covered interest parity, post-GFC CIP deviations and intermediary constraints, and macrofinancial determinants of cross-currency bases. The common lesson is that CIP is a clean no-arbitrage relation in theory, but its enforcement in actual markets uses trading, funding, and balance-sheet capacity. Post-GFC CIP deviations are therefore not simple pricing errors. They are persistent price variables that reflect frictions in international financial markets.

The paper builds on this view but has a different purpose. Existing studies have identified many relevant mechanisms: transaction costs, FX liquidity, dollar funding pressure, intermediary risk-taking capacity, regulation, central bank balance sheets, hedging demand, broad dollar conditions, and term-structure variables. This paper does not replace those explanations. It asks whether a small set of public daily state variables can provide a reproducible benchmark for government-bond CIP deviations.

2.1 Classical CIP and transaction costs

The early CIP literature asks whether covered interest arbitrage profits survive transaction costs in actual foreign exchange markets. [Frenkel and Levich \(1975, 1977\)](#) show that many apparent arbitrage profits are greatly reduced once bid-ask spreads and other transaction costs are taken into account. [Deardorff \(1979\)](#) introduces one-way arbitrage, a weaker arbitrage condition that can still shape foreign exchange market equilibrium.

Later work uses higher-quality and higher-frequency data. [Taylor \(1987\)](#), [Clinton \(1988\)](#), and [Akram et al. \(2008\)](#) show that CIP deviations are usually small in normal market conditions and tend to disappear quickly. These findings support the view that CIP is a strong pricing relation in liquid FX markets.

The key implication is that CIP is not only an accounting identity. It is a tradable relation. The no-arbitrage condition is exact in frictionless theory, but actual arbitrage requires execution, funding, and balance-sheet capacity. A measured CIP deviation therefore need not be a risk-free profit. This paper carries this logic to the post-GFC government-bond setting, where deviations are more persistent and are plausibly linked to broader financial

conditions.

2.2 Post-GFC deviations and intermediary constraints

The post-GFC literature changed the interpretation of CIP deviations. They are no longer viewed only as short-lived pricing errors. They can be persistent objects shaped by intermediary constraints and global dollar funding conditions. [Baba et al. \(2008\)](#) and [Baba and Packer \(2009a,b\)](#) document large dislocations in FX swap and cross-currency swap markets during 2007–2008 and link them to dollar funding stress. [McGuire and von Peter \(2012\)](#) also emphasizes dollar shortages in the global banking system.

Subsequent work shows that CIP deviations persist beyond crisis episodes. [Borio et al. \(2016\)](#) interpret cross-currency bases through balance-sheet costs, regulation, and dollar funding pressure. [Du et al. \(2018a\)](#) document systematic post-GFC CIP deviations across major currencies and link them to intermediary balance-sheet constraints and quarter-end regulatory effects. [Avdjiev et al. \(2019\)](#) connect CIP deviations to the dollar and bank leverage. More recent work, including [Rime et al. \(2022\)](#) and [Ben Zeev and Nathan \(2024\)](#), also emphasizes limited balance-sheet capacity and imbalances in FX swap demand.

This interpretation is closely related to limits-to-arbitrage and intermediary asset pricing. [Brunnermeier and Pedersen \(2009\)](#) show that market liquidity and funding liquidity can reinforce each other. [Gârleanu and Pedersen \(2011\)](#) show that margin constraints can generate law-of-one-price deviations. [He and Krishnamurthy \(2013\)](#) and [Adrian et al. \(2014\)](#) develop the view that intermediary capital and leverage matter for asset prices. The message is similar across these studies: even when a no-arbitrage relation is exact in theory, its enforcement depends on constrained intermediaries. If their funding and balance-sheet capacity are limited, deviations can persist.

For this paper, the important implication is empirical. Many economically natural CIP variables are balance-sheet, regulatory, liquidity, or institutional objects. They are important, but they are often observed at lower frequencies, difficult to reconstruct daily, or not easily available from public sources. This creates a gap between daily CIP deviation panels and the data environment needed to test many structural mechanisms. A public daily benchmark is useful because it separates two questions: how much of government-bond CIP deviations is captured by easily observable macrofinancial state variables, and how much additional power is supplied by richer mechanism-specific variables.

2.3 Macrofinancial determinants and the benchmark role

The closest paper to this study is [Cerutti et al. \(2021\)](#). They study macrofinancial determinants of CIP deviations and show that FX market liquidity, intermediary risk-taking capacity, broad U.S. dollar strength, central bank balance sheets, and term premia are systematically related to cross-currency bases. This paper therefore does not claim that macrofinancial variables are new to the CIP literature. That connection is already well established.

The difference is the role of the specification. Existing work identifies many variables related to CIP deviations, but these variables have not become a standard daily-frequency horse-race benchmark. In empirical asset pricing, standard factor models provide a common hurdle for new factors. Daily CIP work has no equally compact and reproducible public benchmark. A new explanatory variable can therefore look useful relative to an arbitrary straw-man model, even if it adds little beyond simple macrofinancial state variables.

This paper is designed to provide such a hurdle. The benchmark uses only three lagged public variables: the Chicago Fed National Financial Conditions Index (NFCI), the nominal broad U.S. dollar index, and the Treasury 10-year minus 2-year yield slope. These variables summarize financial conditions, the global dollar cycle, and the U.S. yield-curve regime. Each is motivated by prior work, but none is treated as a newly discovered structural determinant. The contribution is to combine them into a compact daily benchmark and to evaluate its in-sample and leave-one-year-out out-of-sample performance.

2.4 Government-bond CIP deviations

This paper focuses on government-bond CIP deviations. [Du and Schreger \(2016\)](#) use local-currency government bonds and currency-hedged returns to study sovereign risk and frictions in international capital markets. [Du et al. \(2018b\)](#) link the special role of U.S. Treasuries to the hedging demand of global investors. [Du and Schreger \(2022\)](#) review the literature on CIP deviations, the dollar, and international capital-market frictions. The government-bond CIP deviation data used in this paper belong to this line of work ([Du et al., 2025a,b](#)).

Government-bond CIP deviations are related to money-market bases, but they also reflect sovereign bond markets, safe-asset demand, hedging demand, and the term structure of interest rates. This motivates the benchmark variables. NFCI captures broad financial conditions. The broad dollar index captures the global dollar regime. The Treasury slope captures the U.S. yield-curve environment. The resulting specification is not a short-term funding-spread model. It is a public macrofinancial state-variable benchmark for the persistent component of government-bond CIP deviations.

The interpretation is empirical rather than structural. Significant coefficients should

not be read as direct evidence for one specific mechanism. Instead, the results show that post-GFC government-bond CIP deviations are strongly aligned with a small set of public macrofinancial state variables. That makes the benchmark useful as a transparent hurdle for richer daily models of CIP deviations.

3 Data and Methodology

This paper studies post-GFC government-bond covered interest parity (CIP) deviations. The dependent variable comes from the government-bond CIP deviation data of [Du et al. \(2025b\)](#). For country i , maturity n , and date t , the government-bond CIP deviation is

$$x_{i,n,t}^{Govt} = y_{i,n,t}^{Govt} - \rho_{i,n,t} - y_{USD,n,t}^{Govt}. \quad (1)$$

Here $y_{i,n,t}^{Govt}$ is the local-currency government-bond yield, $\rho_{i,n,t}$ is the market-implied forward premium for hedging the currency- i cash flow into U.S. dollars, and $y_{USD,n,t}^{Govt}$ is the matched-maturity U.S. Treasury yield. Thus, $x_{i,n,t}^{Govt}$ is the difference between the synthetic dollar yield on a hedged foreign government bond and the direct dollar yield on a U.S. Treasury. I use the variable `cip_govt`, reported in basis points.

The sample runs from January 1, 2008 to June 30, 2025. It covers currency-tenor panels for G10 currencies plus the Korean won. G10 currencies form the core sample in the post-GFC CIP literature. The Korean won is added as a major open-economy currency from an advanced Asian financial market. I denote the government-bond CIP deviation for currency c , tenor τ , and date t by $CIP_{c,\tau,t}$.

The benchmark uses three public macrofinancial state variables. The Chicago Fed National Financial Conditions Index (NFCI) summarizes broad financial conditions and intermediary constraints ([FRED, 2026](#)). The nominal broad U.S. dollar index captures the global dollar cycle ([FRED, 2026d](#)). The Treasury 10-year minus 2-year yield slope summarizes the U.S. yield-curve regime ([FRED, 2026b,a](#)).

The variables are aligned with the information set available at date t . NFCI is weekly. I use the previous weekly print and carry it forward to the daily CIP calendar. The broad dollar index is daily, but it can be missing on some CIP trading days. I carry forward the most recent available observation and then use a one-observation lag. The Treasury slope is constructed as

$$Slope_{t-1} = DGS10_{t-1} - DGS2_{t-1},$$

and is also lagged by one observation. Thus, $NFCI_{t-1}$ denotes the latest lagged weekly NFCI print available at date t , while $Dollar_{t-1}$ and $Slope_{t-1}$ denote the lagged broad dollar

index and Treasury slope.

I interpret these variables as compact state variables, not as separately identified structural channels. NFCI summarizes broad financial conditions rather than one specific friction. The Treasury slope may reflect term premia, monetary-policy expectations, business-cycle conditions, and long-bond supply and demand. The broad dollar index captures the global dollar environment. The goal is to build a low-dimensional public benchmark, not to replace richer mechanism-specific proxies.

The main benchmark regression is

$$CIP_{c,\tau,t} = \alpha_{c,\tau} + \beta_{c,\tau}^N NFCI_{t-1} + \beta_{c,\tau}^D Dollar_{t-1} + \beta_{c,\tau}^S Slope_{t-1} + \varepsilon_{c,\tau,t}. \quad (2)$$

I estimate this equation separately for each currency–tenor panel. The specification is intentionally small: it uses three public state variables and panel-specific intercepts.

In-sample fit is measured by a within-panel R^2 . For each currency–tenor panel, I compute the total sum of squares around that panel’s own mean. I then sum residual and total sums of squares across panels. This prevents the statistic from mechanically rewarding the model for matching average level differences across currencies or tenors.

Out-of-sample performance is evaluated by leave-one-year-out (LOYO) tests. I exclude one calendar year at a time, estimate the model on the remaining years, and predict the excluded year. The LOYO R^2 compares holdout observations with the training-sample mean within the same currency–tenor panel. This benchmark already allows each panel to have its own average level.

I also estimate two stacked specifications. The first is a currency-level common-slope specification. For each currency c , I stack all tenors and include tenor fixed effects:

$$CIP_{c,\tau,t} = \alpha_c + \lambda_{\tau,c} + \beta_c^N NFCI_{t-1} + \beta_c^D Dollar_{t-1} + \beta_c^S Slope_{t-1} + u_{c,\tau,t}. \quad (3)$$

This specification allows tenor-level differences within each currency, but restricts the three state-variable slopes to be common across tenors.

The second is a pooled common-slope specification. I stack all currencies and tenors and include currency and tenor fixed effects:

$$CIP_{c,\tau,t} = \alpha + \mu_c + \lambda_\tau + \beta^N NFCI_{t-1} + \beta^D Dollar_{t-1} + \beta^S Slope_{t-1} + v_{c,\tau,t}. \quad (4)$$

Together, the stacked specifications test whether the benchmark’s performance depends on freely estimated currency–tenor slopes.

For inference, I use Newey–West HAC standard errors. The daily level regressions use a

21-trading-day lag, roughly one trading month. In stacked regressions, many currencies and tenors are observed on the same date. I therefore aggregate scores by date before computing the HAC covariance matrix, which reduces the risk that cross-sectional stacking understates standard errors.

I use two residual-based Engle–Granger diagnostics. The first tests the relation between actual CIP deviations and baseline fitted values. The second tests the relation between actual CIP deviations and the three baseline regressors directly. These tests are not causal evidence. They are diagnostic checks against purely spurious level correlation.

Finally, I run an aggregation-difference analysis. For each currency–tenor panel, I sort observations by date and form non-overlapping N -trading-day blocks. I average the CIP deviation and the three regressors within each block, then take differences across adjacent blocks:

$$\Delta_N CIP_{c,\tau,b} = a_{c,\tau} + b_{c,\tau}^N \Delta_N NFCI_b + b_{c,\tau}^D \Delta_N Dollar_b + b_{c,\tau}^S \Delta_N Slope_b + e_{c,\tau,b}, \quad (5)$$

where b indexes non-overlapping aggregation blocks. This design asks whether the benchmark explains only persistent levels or also lower-frequency changes. Because the blocks do not overlap, it reduces mechanical serial correlation from overlapping differences. HAC lags for the differenced regressions use a conservative multiple of an automatic lag rule.

The empirical design therefore has three steps. I first estimate a compact level benchmark using public state variables. I then evaluate out-of-sample performance and test whether slopes transport across tenors. Finally, I use cointegration and aggregation-difference diagnostics to assess whether the relation reflects stable low-frequency alignment rather than a spurious level fit.

4 Empirical Results

This section evaluates the three-variable benchmark. The model is not a structural explanation of CIP deviations. Its purpose is more limited: to test whether lagged NFCI, the lagged broad dollar index, and the lagged Treasury 10-year minus 2-year slope summarize a large component of post-GFC government-bond CIP deviations.

The results are strong for such a small specification. The benchmark delivers high in-sample fit, survives leave-one-year-out (LOYO) out-of-sample tests, and has economically interpretable coefficient patterns.

4.1 Overall fit

[Table 4.1](#) reports the main fit statistics. In separate currency–tenor regressions, the within-panel in-sample R^2 is 0.637. This is a conservative statistic. It removes average level differences within each currency–tenor panel, so the fit is not driven mechanically by matching currency or tenor means.

Out-of-sample performance is also strong. The separate currency–tenor specification has a LOYO pooled R^2 of 0.499. The simple average of holdout-year R^2 values is 0.347. Thus, coefficients estimated without a given calendar year still predict that excluded year better than the training-sample panel mean.

The fit does not rely only on freely estimated currency–tenor slopes. In the currency-specific common-slope specification, all tenors are stacked within each currency and tenor fixed effects are included. This specification has an in-sample R^2 of 0.645 and a LOYO pooled R^2 of 0.607. The pooled common-slope specification, with currency and tenor fixed effects, has an in-sample R^2 of 0.658.

Table 4.1: Baseline fit and out-of-sample performance

Specification	In-sample R^2	LOYO pooled R^2	LOYO mean-year R^2
Separate currency–tenor regressions	0.637	0.499	0.347
Currency-specific common-slope regressions	0.645	0.607	0.509
Pooled common-slope regression	0.658	–	–

Notes: The baseline specification uses lagged NFCI, the lagged nominal broad dollar index, and the lagged Treasury 10-year minus 2-year yield slope. Separate currency–tenor regressions estimate one regression for each currency–tenor panel. Currency-specific common-slope regressions stack all tenors within each currency and include tenor fixed effects. The pooled common-slope regression stacks all currencies and tenors and includes currency and tenor fixed effects. LOYO denotes leave-one-year-out evaluation. In-sample R^2 uses a within-panel denominator. LOYO R^2 uses the training-sample mean as the benchmark.

The maturity profile is also informative. [Table 4.2](#) summarizes the separate currency–tenor fits by tenor. The benchmark is strongest at intermediate maturities. Mean R^2 rises from 0.391 at the 3-month tenor to 0.615 at the 5-year tenor, and remains high at the 7-year tenor. Fit is weaker at the very short end and at the 20-year tenor. This pattern suggests that the benchmark is not just capturing short-horizon money-market noise. It is most closely aligned with the middle part of the government-bond CIP term structure.

Table 4.2: Tenor profile of separate currency–tenor fits

Tenor	Currencies	Observations	Mean R^2	Median R^2	Range of R^2
0.25	11	49,205	0.391	0.379	[0.160, 0.696]
1	11	48,036	0.454	0.409	[0.182, 0.887]
2	11	48,468	0.522	0.498	[0.219, 0.903]
3	11	48,265	0.585	0.608	[0.284, 0.871]
5	11	48,404	0.615	0.631	[0.254, 0.825]
7	11	48,339	0.563	0.610	[0.286, 0.782]
10	11	48,395	0.465	0.421	[0.156, 0.757]
20	11	43,892	0.378	0.297	[0.147, 0.682]
30	10	36,809	0.421	0.505	[0.149, 0.665]

Notes: The table summarizes full-sample separate currency–tenor regressions by tenor. For each tenor, R^2 statistics are computed across available currencies. The observations column reports the total number of observations across currencies at each tenor. The 30-year tenor is available for 10 currencies.

Figure 4.1 plots actual CIP deviations against fitted values. The figure shows a strong common component, but also substantial residual dispersion. This is the intended interpretation. The benchmark captures a large macrofinancial component of government-bond CIP deviations, but it is not a complete structural model.

Figure 4.1: Actual CIP deviations and baseline fitted values. The out-of-sample fitted values are generated from the leave-one-year-out specification.

4.2 Out-of-sample performance

4.2.1 Leave-one-year-out validation

The first out-of-sample exercise is LOYO validation. This is not a fully chronological forecast, because the training sample for a holdout year can include later observations. Its purpose is different. It applies the same exclusion rule to every calendar year and tests whether the fit is concentrated in a few favorable episodes.

Figure 4.2: Leave-one-year-out out-of-sample performance

Figure 4.2 reports LOYO performance by holdout year. The separate currency–tenor specification delivers positive pooled R^2 values in most years. The exceptions are 2014, 2017, and 2018. Thus, the benchmark does not fit every market environment mechanically. Even so, the full-sample LOYO pooled R^2 remains high at 0.499.

The currency-specific common-slope specification is more stable. It estimates common state-variable slopes within each currency and allows tenor fixed effects. Its LOYO pooled R^2 is 0.607. This shows that substantial out-of-sample fit remains even when the model does not freely estimate every currency–tenor slope.

Table 4.3 reports the currency-specific common-slope results by currency. Most currencies show strong in-sample and out-of-sample performance. CAD, EUR, KRW, DKK, and SEK are especially strong. JPY is weaker. The key point is that the benchmark is not driven by one or two currencies.

Table 4.3: Currency-specific common-slope performance

Currency	Observations	In-sample R^2	LOYO pooled R^2
AUD	37,945	0.497	0.350
CAD	39,842	0.799	0.776
CHF	39,750	0.551	0.486
DKK	38,987	0.595	0.546
EUR	39,898	0.651	0.603
GBP	39,563	0.491	0.429
JPY	38,252	0.242	0.134
KRW	35,400	0.746	0.746
NOK	37,163	0.497	0.404
NZD	34,550	0.581	0.529
SEK	38,463	0.630	0.544

Notes: For each currency, all tenors are stacked. The specification includes tenor fixed effects and common slopes on lagged NFCI, the lagged nominal broad dollar index, and the lagged Treasury 10-year minus 2-year yield slope. LOYO R^2 uses the training-sample currency mean as the benchmark.

4.2.2 Expanding-window forecasts

As a stricter time-ordered check, I also estimate expanding-window forecasts. The initial training window uses the first three sample years. The model is then re-estimated recursively using only past data, and the fitted coefficients are used to predict the next calendar year. This design avoids using future observations when evaluating a holdout year.

Figure 4.3 and Table 4.4 report the results. The baseline remains strong under this chronological design. The expanding-window pooled R^2 is 0.503 over 2011–2025, close to the LOYO pooled R^2 of the separate currency–tenor specification. The simple average of yearly pooled R^2 values is 0.495. All holdout years have positive pooled R^2 . The weakest years are 2015, 2018, 2020, and 2022, but even these remain positive on the pooled metric.

Figure 4.3: Expanding-window out-of-sample performance

Table 4.4: Expanding-window out-of-sample performance by holdout year

Holdout year	Observations	Panels	Pooled R^2	Median panel R^2
2011	22,906	90	0.540	0.465
2012	23,757	92	0.434	0.564
2013	23,806	92	0.652	0.395
2014	25,019	97	0.632	0.472
2015	24,541	97	0.146	-0.894
2016	24,390	97	0.720	0.225
2017	24,251	97	0.414	-0.119
2018	24,191	97	0.239	0.079
2019	24,092	97	0.527	0.309
2020	24,042	97	0.299	0.206
2021	23,685	97	0.609	0.438
2022	22,667	97	0.317	0.342
2023	23,181	97	0.534	0.424
2024	23,229	97	0.695	0.560
2025	11,463	98	0.667	0.456
All years	345,220	1,439	0.503	—
Mean year	—	—	0.495	0.261

Notes: The initial training window uses the first three sample years. The model is re-estimated recursively using only past data to predict each subsequent holdout year. Pooled R^2 aggregates squared forecast errors across all test observations in the holdout year. Median panel R^2 is the median across currency–tenor panels within the holdout year. The all-years pooled R^2 aggregates all expanding-window test observations.

Panel-level performance is more heterogeneous. The median currency–tenor panel R^2 is positive in 13 of the 15 expanding-window holdout years, with an average yearly median panel R^2 of 0.261. This median statistic is useful because some currency–tenor panels produce very poor year-specific forecasts, which makes the simple mean of panel R^2 values sensitive to outliers. The expanding-window evidence therefore supports the main result, while also showing that the benchmark is a compact macrofinancial summary rather than a complete panel-by-panel forecasting model.

4.3 Coefficient structure

Table 4.5 summarizes coefficient signs and significance from 98 separate currency–tenor regressions. NFCI is the most stable variable. Its coefficient is positive in 88.8% of panels and significant at the 5% level in 86.7%. Among significant NFCI coefficients, 80 are positive and only 5 are negative. This is consistent with the view that tighter financial conditions widen CIP deviations.

The Treasury slope also has a stable sign pattern. Its coefficient is positive in 85.7% of panels and significant at the 5% level in half of the panels. Almost all significant slope coefficients are positive. This suggests that the U.S. yield-curve regime explains part of the persistent component not captured by NFCI and the broad dollar.

The broad dollar coefficient is more heterogeneous. It is significant at the 5% level in 37.8% of panels, but its sign varies across currencies and tenors. This is consistent with the broad dollar acting as a global state variable whose effect depends on currency-specific funding and hedging pressures.

Table 4.5: Coefficient signs and significance in separate currency–tenor regressions

Variable	Mean coefficient	Median coefficient	Positive share	5% significant share	Significant positive	Significant negative
NFCI	22.954	18.808	0.888	0.867	80	5
Broad dollar	-0.037	-0.090	0.429	0.378	23	14
Treasury slope	9.623	10.312	0.857	0.500	48	1

Notes: The table summarizes coefficients from 98 separate currency–tenor regressions. The 5% significant share is the fraction of panels with HAC p -values below 0.05. Significant positive and significant negative count coefficients that are positive or negative and significant at the 5% level.

Overall, the results deliver three messages. First, three public state variables explain a large part of post-GFC government-bond CIP deviations. Second, the fit is not driven only

by separate currency–tenor slopes; it remains strong in common-slope specifications. Third, the coefficient structure is economically sensible. NFCI and the Treasury slope show stable positive patterns, while the broad dollar captures heterogeneous exposure to the global dollar regime. The baseline is therefore a simple and reproducible public-data benchmark for future work on CIP deviations.

5 Robustness

This section clarifies the scope of the benchmark. I examine four issues. First, I test whether the results are affected by the quarter-end regulatory effects emphasized in the post-GFC CIP literature. Second, I use Engle–Granger diagnostics to assess whether the level fit is only a common-trend artifact. Third, I use non-overlapping aggregation differences to ask whether the relation also appears in lower-frequency changes. Fourth, I rotate the three state variables into principal components to test whether the benchmark is merely a proxy for one or two broad common factors.

The results support a narrow interpretation. The benchmark is not a model of ultra-short quarter-end spikes or daily execution noise. It is a public-data benchmark for the persistent macrofinancial component of government-bond CIP deviations.

5.1 Quarter-end dummy extension

A prominent result in the post-GFC CIP literature is that CIP deviations move around quarter ends. [Du et al. \(2018a\)](#) show that the effect is especially sharp at very short maturities. One-month deviations rise when one-month contracts begin to cross quarter-end reporting dates, and one-week deviations rise when one-week contracts cross quarter ends.

The present data are not designed to isolate that mechanism. The government-bond CIP deviation data of [Du et al. \(2025b\)](#) start at the three-month tenor. Three-month contracts are less suited for detecting the discrete quarter-end crossing effect, because they appear on quarter-end balance sheets regardless of the initiation date within the quarter.

To check whether this matters for the benchmark, I augment the baseline with a short-tenor quarter-end dummy. The main version uses the last five observed trading days of each calendar quarter:

$$QEndShort_{\tau,t}^{(5)} = \mathbf{1}\{\tau \leq 1\}\mathbf{1}\{t \in QEnd^{(5)}\},$$

where $QEnd^{(5)}$ denotes the last five observed trading days of each calendar quarter. The dummy is active only for tenors of one year or less. This window allows quarter-end balance-sheet pressure to be reflected gradually before the reporting date. I also check a narrower

version that activates only on the final observed trading day of each quarter.

The results are economically negligible. The five-day quarter-end dummy changes the in-sample R^2 by less than 0.0001 and does not improve leave-one-year-out performance. The narrower one-day dummy gives the same conclusion. The dummy coefficients are also not systematically significant under HAC inference. Thus, the main benchmark is not materially affected by quarter-end dummy adjustments.

This finding should not be read as evidence against the quarter-end mechanism in [Du et al. \(2018a\)](#). It reflects the maturity structure of the present sample. The sharp quarter-end regulatory effect is primarily a very-short-tenor phenomenon, whereas this paper studies government-bond CIP deviations at maturities of three months and longer. The benchmark is therefore best interpreted as a model of background government-bond CIP deviations, not ultra-short-maturity reporting-date spikes.

5.2 Engle–Granger cointegration diagnostics

The high level-regression R^2 raises a standard concern: persistent series can appear related even when there is no stable economic relation. I use Engle–Granger residual-based tests as a diagnostic check against this possibility.

I run two tests. The first is a compressed actual–fitted diagnostic. It tests whether actual CIP deviations and baseline fitted values share a stable long-run relation. The second is closer to the baseline regression itself. It tests whether actual CIP deviations are cointegrated with the three baseline regressors: *NFCI*, *Dollar*, and *Slope*.

[Table 5.1](#) reports the rejection counts. At the currency–tenor level, the multivariate test using the three regressors rejects the no-cointegration null in 98 of 98 panels at the 5% level under the constant specification. It rejects in 96 of 98 panels at the 1% level. With a constant and trend, the rejection counts remain high: 97 of 98 at the 5% level and 94 of 98 at the 1% level.

The actual–fitted diagnostic is also strong. At the currency–tenor level, it rejects the no-cointegration null in all 98 panels at the 5% level. The 1% rejection count is 98 of 98 under the constant specification and 97 of 98 under the constant-plus-trend specification. Currency-level and global aggregate series reject the null in all cases, including at the 1% level.

Table 5.1: Engle–Granger cointegration diagnostics

Unit	Test relation	Deterministic term	5% reject	1% reject
Currency–tenor panel	Actual $\sim$ regressors	Constant	98/98	96/98
Currency–tenor panel	Actual $\sim$ regressors	Constant + trend	97/98	94/98
Currency–tenor panel	Actual $\sim$ fitted value	Constant	98/98	98/98
Currency–tenor panel	Actual $\sim$ fitted value	Constant + trend	98/98	97/98
Currency aggregate	Actual $\sim$ regressors	Constant	11/11	11/11
Currency aggregate	Actual $\sim$ regressors	Constant + trend	11/11	11/11
Currency aggregate	Actual $\sim$ fitted value	Constant	11/11	11/11
Currency aggregate	Actual $\sim$ fitted value	Constant + trend	11/11	11/11
Global aggregate	Actual $\sim$ regressors	Constant	1/1	1/1
Global aggregate	Actual $\sim$ regressors	Constant + trend	1/1	1/1
Global aggregate	Actual $\sim$ fitted value	Constant	1/1	1/1
Global aggregate	Actual $\sim$ fitted value	Constant + trend	1/1	1/1

Notes: Each cell reports the number of series for which the no-cointegration null is rejected. “Actual $\sim$ regressors” refers to the multivariate Engle–Granger test linking actual CIP deviations to *NFCI*, *Dollar*, and *Slope*. “Actual $\sim$ fitted value” refers to the compressed Engle–Granger test between actual CIP deviations and baseline fitted values. Currency and global aggregates use daily median aggregate series.

These results reduce the concern that the baseline level fit is only a spurious common-trend artifact. The evidence is strongest in the multivariate test, where actual CIP deviations are linked directly to the three baseline state variables.

The interpretation remains diagnostic, not causal. The Engle–Granger tests show stable long-run alignment. They do not show that any one regressor structurally causes CIP deviations. A more modest conclusion is appropriate: *NFCI*, the broad dollar, and the Treasury slope compress macrofinancial forces that are stably aligned with the persistent component of post-GFC government-bond CIP deviations.

5.3 Non-overlapping aggregation-difference analysis

The next diagnostic asks whether the benchmark only explains persistent levels. For each currency–tenor panel, I sort observations by date and form non-overlapping N -trading-day blocks. I average the CIP deviation and the three regressors within each block, then difference adjacent blocks:

$$\Delta_N CIP_{c,\tau,b} = a_{c,\tau} + b_{c,\tau}^N \Delta_N NFCI_b + b_{c,\tau}^D \Delta_N Dollar_b + b_{c,\tau}^S \Delta_N Slope_b + e_{c,\tau,b}.$$

Here b indexes non-overlapping aggregation blocks. This design tests whether the relation appears in changes measured over horizons from one day to roughly three months. The non-overlapping construction reduces mechanical serial correlation from overlapping differences, but the effective sample size falls as N increases.

Table 5.2 reports the results for selected aggregation windows. The pattern is simple. At high frequencies, the benchmark explains almost nothing. At intermediate horizons, the relation reappears. At longer horizons, the pooled evidence remains positive, but annual panel-level evaluation becomes noisy because the number of non-overlapping blocks is small.

For $N = 1$ and $N = 5$, explanatory power is close to zero. The in-sample R^2 is 0.007 at $N = 1$ and 0.047 at $N = 5$. The LOYO pooled R^2 is also near zero. This is consistent with the design of the benchmark. Three lagged macrofinancial state variables are not meant to predict daily execution noise, flow imbalances, or dealer inventory shocks.

The relation becomes stronger at monthly-to-quarterly horizons. The in-sample R^2 rises to 0.218 at $N = 21$, 0.313 at $N = 32$, and 0.369 at $N = 50$. The LOYO pooled R^2 is also positive over these windows, reaching 0.254 at $N = 50$. Thus, the benchmark explains not only persistent levels, but also a meaningful share of lower-frequency changes.

The LOYO mean-year R^2 becomes negative at longer N . This statistic should be interpreted cautiously. The number of differenced observations falls from 419,715 at $N = 1$ to 6,505 at $N = 63$. Once these observations are split across 98 panels and calendar-year holdouts, each year-by-panel cell contains only a small number of non-overlapping blocks. The mean-year statistic is therefore high variance. It can turn negative even when the pooled R^2 remains positive.

Table 5.2: Non-overlapping aggregation-difference performance

Aggregation window N	In-sample R^2	LOYO pooled R^2	LOYO mean-year R^2	Observations
1	0.007	-0.001	0.004	419,715
5	0.047	0.026	-0.006	83,823
21	0.218	0.161	-0.045	19,848
32	0.313	0.234	-0.049	12,951
50	0.369	0.254	-0.060	8,232
63	0.412	0.217	-0.115	6,505

Notes: For each N , I form non-overlapping N -trading-day block averages and difference adjacent blocks. In-sample R^2 uses a within-panel denominator based on panel-specific differenced means. LOYO R^2 uses the training-sample panel-specific differenced mean as the benchmark. Observations report the total number of differenced observations across all currency-tenor panels.

Figure 5.1 plots the in-sample and out-of-sample R^2 values across aggregation windows. The figure reinforces the table. The benchmark explains little of daily changes. Its explanatory power rises once the horizon reaches several weeks. The pooled LOYO curve tracks the in-sample curve at intermediate windows and remains positive throughout.

Figure 5.1: Non-overlapping aggregation-difference performance

The aggregation-difference evidence sharpens the interpretation of the benchmark. The relation is weak at daily horizons, meaningful at monthly-to-quarterly horizons, and harder to estimate precisely at long non-overlapping windows. This is consistent with a persistent macrofinancial component rather than a high-frequency arbitrage-execution model.

5.4 Principal component analysis

As a final diagnostic, I rotate the three baseline state variables into principal components. This asks whether the benchmark is mostly a proxy for one or two broad common factors, or whether the full three-variable state space matters. The PCA is applied to the standardized baseline regressors: lagged NFCI, the lagged nominal broad dollar index, and the lagged Treasury 10-year minus 2-year slope.

Table 5.3 reports the fit. The first principal component explains 64.1% of the variation in the state variables, but it delivers only an in-sample R^2 of 0.353 and a negative expanding-window pooled R^2 . Adding the second component raises the in-sample R^2 to 0.613, but the expanding-window pooled R^2 remains low at 0.033. The full three-component rotation reproduces the baseline by construction and restores the expanding-window pooled R^2 of 0.503.

Table 5.3: PCA robustness: fit

Model	Cumulative state variance	In-sample R^2	Expanding pooled R^2	Mean yearly pooled R^2
PC1	64.1%	0.353	-0.043	0.040
PC1–PC2	95.1%	0.613	0.033	0.112
PC1–PC3	100.0%	0.637	0.503	0.495
Baseline	–	0.637	0.503	0.495

Notes: The PCA is computed from standardized baseline state variables. The first three rows report fit using the first k principal components as regressors. The full three-component rotation spans the same regressor space as the baseline, so its fit matches the baseline up to numerical precision.

Table 5.4 reports the loadings. PC1 mainly contrasts the broad dollar with the Treasury slope. PC2 is dominated by NFCI. PC3 loads positively on both the broad dollar and the Treasury slope. Although PC3 explains only a small share of state-variable variance, it is needed to recover the benchmark’s out-of-sample performance.

Table 5.4: PCA loadings

State variable	PC1	PC2	PC3
NFCI	-0.263	0.965	0.018
Broad dollar	0.684	0.174	0.709
Treasury 10Y–2Y slope	-0.681	-0.199	0.705

Notes: Loadings are computed from the standardized baseline state variables. The sign of each principal component is arbitrary.

The PCA evidence rules out a simple common-factor interpretation. The first two components explain 95.1% of state-variable variation, but they do not recover the expanding-window performance of the original benchmark. The low-variance third component is needed. The benchmark therefore does not appear to be a redundant proxy for one or two broad factors. Its performance depends on the full combination of NFCI, the broad dollar, and the Treasury slope.

Taken together, the robustness tests support the benchmark interpretation. The results are not explained by a short-tenor quarter-end dummy. The level relation passes residual-based cointegration diagnostics. The relation appears in lower-frequency changes, but not in daily noise. The PCA results show that the full three-variable state space matters. The benchmark should therefore be read as a compact public-data model of the persistent macro-financial component of post-GFC government-bond CIP deviations.

6 Discussion

The results should be read as a benchmark result, not as a structural model of CIP deviations. The baseline uses three public state variables. NFCI summarizes broad financial conditions. The broad dollar index summarizes the global dollar regime. The Treasury 10-year minus 2-year slope summarizes the U.S. yield-curve environment. These variables compress several macrofinancial forces, but they do not identify a single mechanism. Nor do they imply that only three forces drive government-bond CIP deviations.

The central result is narrower. A small public-data specification explains a large persistent component of daily government-bond CIP deviations. The model is easy to replicate and strong enough that it should not be treated as a straw man. This section discusses how the benchmark should be used, where it performs less well, and how it relates to richer explanations.

6.1 How the benchmark should be used

The benchmark is meant to be a hurdle for future empirical work. A researcher who proposes a new funding variable, regulatory proxy, liquidity measure, balance-sheet variable, hedging-demand proxy, or structural model should ask whether it improves on this baseline. Statistical significance in isolation is not enough. The relevant test is incremental explanatory power relative to a compact public-data specification.

This comparison can be implemented as a horse race. A richer model should be tested against the baseline both in sample and out of sample. It should also show that the improve-

ment is not driven by one currency, one tenor, or one favorable holdout year. In this sense, the baseline provides a common yardstick for daily government-bond CIP regressions.

This role is useful because many important CIP determinants are hard to observe at daily frequency. Dealer balance-sheet capacity, bank-level constraints, specialized liquidity measures, regulatory exposures, and hedging flows are often proprietary, low-frequency, or difficult to reconstruct. The public benchmark does not replace these variables. It gives them a transparent comparison model.

6.2 Currency-level heterogeneity

The baseline is deliberately dollar-centered. This is natural for CIP deviations, but it also limits what the model can explain. NFCI, the broad dollar, and the Treasury slope are U.S. or global-dollar state variables. Their effects need not be identical across currencies. Currency-specific funding structures, hedging demand, local bond markets, safe-asset roles, and domestic institutions can all affect the mapping from global state variables to CIP deviations.

The results show this heterogeneity. CAD, EUR, KRW, DKK, and SEK perform well in the currency-level common-slope specification. JPY is weaker. The model captures part of the common movement in JPY, but it misses several level shifts, especially in later holdout years. This is consistent with a larger local component that is not spanned by the three U.S.-centered state variables.

The weaker cases are informative rather than fatal. Some currencies are difficult only at specific maturities. For example, performance is weaker for some long-tenor SEK panels and some short- or intermediate-tenor AUD panels. This suggests that the missing component is partly currency-specific and partly tenor-specific. Local curve conditions, maturity-specific hedging pressure, and segmented investor demand may matter in ways that the baseline does not capture.

This does not undermine the benchmark interpretation. A useful benchmark should be portable and disciplined. It should not absorb every local market feature. Weak currency-tenor cells show where richer models have room to add value. A successful extension should explain these residual patterns, not only raise pooled R^2 .

6.3 Regime dependence and frequency scope

The out-of-sample results also show regime dependence. The benchmark performs well in most holdout years, but not equally in every year. This is expected. Government-bond CIP deviations reflect balance-sheet capacity, dollar funding, hedging imbalances, regulation,

safe-asset demand, and market liquidity. The relative importance of these forces can change across regimes.

The quarter-end dummy exercise clarifies the maturity scope of the paper. [Du et al. \(2018a\)](#) emphasize sharp quarter-end regulatory effects, especially at very short maturities. The data used here begin at the three-month tenor. A short-tenor quarter-end dummy adds essentially no explanatory power to the baseline. This does not contradict the quarter-end mechanism. It means that the present benchmark is aimed at the persistent background component of government-bond CIP deviations, not at ultra-short-maturity reporting-date spikes.

The aggregation-difference results point to the same interpretation. The baseline explains little of daily changes. Its explanatory power rises when changes are measured over several weeks or months. The model should therefore not be interpreted as a high-frequency execution model. It is better understood as a compact description of the low-frequency macrofinancial component of post-GFC government-bond CIP deviations.

6.4 Relation to richer macrofinancial explanations

The benchmark complements the macrofinancial determinants literature. It does not replace it. [Cerutti et al. \(2021\)](#), for example, relate cross-currency bases to FX market liquidity, intermediary risk-taking capacity, broad dollar strength, central bank balance sheets, and term premia. Other work emphasizes bank balance sheets, regulatory constraints, dollar funding stress, quarter-end effects, and hedging imbalances. These mechanisms remain central for understanding why CIP deviations exist.

The contribution here is to ask how far one can go before using lower-access variables. The answer is: surprisingly far, but not all the way. The three public state variables capture a large common component. They leave meaningful residual heterogeneity across currencies, tenors, and regimes. That residual heterogeneity is where structural work and richer data should matter.

Overall, post-GFC government-bond CIP deviations are not purely idiosyncratic pricing errors. They are persistent price variables aligned with public macrofinancial conditions. The alignment is strong but incomplete. The combination of NFCI, the broad dollar index, and the Treasury slope therefore provides a simple, reproducible, and empirically strong benchmark for future work on daily government-bond CIP deviations.

7 Conclusion

This paper proposes a compact public-data benchmark for post-GFC government-bond covered interest parity (CIP) deviations. The motivation is practical. CIP deviations are observed at daily frequency, but the empirical CIP literature has not converged on a canonical daily-frequency benchmark. Many important determinants—intermediary balance-sheet constraints, dollar funding conditions, regulation, hedging demand, liquidity, and term premia—are lower-frequency, difficult to reconstruct, or not equally portable across research environments. The paper asks how far one can go before using these richer variables.

The answer is: surprisingly far. A baseline with only three lagged public state variables—the Chicago Fed NFCI, the nominal broad U.S. dollar index, and the Treasury 10-year minus 2-year yield slope—summarizes a large component of G10+KRW government-bond CIP deviations. The fit is strong in separate currency–tenor regressions, in currency-level common-slope specifications, and in pooled common-slope specifications. It also remains strong in leave-one-year-out out-of-sample tests. The result is therefore not merely an in-sample artifact of a flexible panel specification.

The coefficient patterns are consistent with a macrofinancial interpretation. NFCI is the most stable regressor and enters positively in most panels, consistent with tighter financial conditions widening CIP deviations. The Treasury slope also tends to enter positively, suggesting that the U.S. yield-curve regime is linked to the persistent component of government-bond CIP deviations. The broad dollar coefficient is more heterogeneous, consistent with the global dollar cycle interacting with currency-specific funding and hedging pressures.

The robustness exercises clarify the scope of the benchmark. A short-tenor quarter-end dummy adds essentially no explanatory power. This does not contradict the quarter-end mechanism emphasized by [Du et al. \(2018a\)](#); it reflects the maturity structure of the present data, which begin at the three-month tenor. Engle–Granger diagnostics reduce the concern that the level fit is only a common-trend artifact. Aggregation-difference tests show that the benchmark explains little of daily high-frequency changes, but becomes more informative over several-week to several-month horizons. The specification is therefore not a high-frequency arbitrage-execution model. It is a reduced-form benchmark for the persistent macrofinancial component of government-bond CIP deviations.

The contribution is not a new individual state variable or a structural identification result. NFCI, the broad dollar, and the Treasury slope are all motivated by existing work. The contribution is to show that their combination forms a simple, reproducible, and empirically strong daily benchmark. This benchmark provides a common hurdle for future work. Richer funding variables, regulatory proxies, intermediary balance-sheet measures, liquidity

measures, hedging-demand variables, or structural models should show incremental power relative to it, both in sample and out of sample, and across currencies and tenors.

In sum, post-GFC government-bond CIP deviations are not purely idiosyncratic pricing errors. They are persistent price variables aligned with observable macrofinancial conditions. This paper does not replace structural models of CIP deviations. It provides a portable public-data benchmark for the background component that such models should be compared against.
