Abstract

Reinforcement learning has increasingly been used to study economic decision-making, such as taxation, public spending, and labour supply. However, most existing RL-based economic models focus on a single government–household group, thereby overlooking the strategic interactions that arise when multiple governments compete while managing their own populations. In practice, many economic systems (e.g., taxation) exhibit a multi-group structure, where each government must optimize its fiscal policy in response not only to household behaviour within its jurisdiction, but also to the policies of other competing governments. To capture this structure, we formulate taxation as a hierarchical multi-group game. Within each group, the interaction between the government and households is modelled as a leader–follower game; across groups, governments are modelled as players in a competitive game. This results in a hybrid hierarchical game that is difficult to solve using standard multi-agent reinforcement learning algorithms. We therefore propose a bi-level training framework built on multi-agent reinforcement learning, together with *Curriculum Learning* and a *Closed-Loop Sequential Update* strategy, to stabilize training and promote convergence. We instantiate this framework in a taxation game simulation environment grounded in classical economic models. The environment supports the evaluation of different taxation algorithms and provides multiple economic indicators for assessing policy performance. Experiments show that our approach can learn stable tax policies that benefit all participating groups. Compared with a two-group baseline without the proposed update mechanisms, our method avoids premature game collapse, extends the effective game duration by 60.92%, produces more sustainable and robust tax policies, and reduces GDP disparities among governments by 44.12%.

1 Introduction

The study of socio-economic models plays a pivotal role in forecasting economic trends and facilitating effective macroeconomic regulation [15, 16]. However, modeling such systems faces several

critical challenges. On the one hand, real-world economic environments are inherently complex and involves diverse entities, such as governments, households, firms, and banks, which makes it difficult to capture the ideal interactions among these entities [4]. On the other hand, the heterogeneity of these systems present extra obstacles. Real-world scenarios generally involve thousands of heterogeneous entities, each possessing distinct observation and action spaces. This high-dimensional complexity makes the optimization of economic policies across different agents a formidable challenge [27].

Multi-Agent Reinforcement Learning (MARL) provides a promising pathway to overcome these limitations. For instance, the AI Economist [28] proposed a bi-level architecture to model the interaction between the government and households within a single region, utilizing bi-level RL algorithms to effectively simulate tax policy dynamics. Building on this, TaxAI [19] refined the underlying economic model and leveraged mean-field theory to scale up the household population for higher fidelity. these two reference should be used to emphasize MARL methods. you can mention bilevel structure, no need to mention mean field approach and scability issue. Simply mention these two works leverage MARL to address economic simulation. Despite their effectiveness in optimizing domestic policies, these approaches are limited by their exclusive focus on the interactions within a single group (i.e., intra-group), where interaction dynamics is generally modeled as a Stackelberg game [24] with a leader-follower structure. While in reality, competitions among groups (i.e., inter-group) are also indispensable for economics. Such inter-group interactions can be captured by the competition between the leader agents like governments in different groups. For instance, the tariff competition. This forces the governments to adapt their strategies not only to their residents but also to rival governments. This structural heterogeneity poses challenges for conventional bi-level MARL frameworks, which are typically designed for a single-group game and thus struggle to optimize across two fundamentally different interaction paradigms simultaneously.

To address this gap, we introduce the *Multi-group Hierarchical Game* formulation (MHG), a novel framework that models hybrid strategic interactions among heterogeneous agents across multiple competing groups. Building upon MHG, we develop a multi-group MARL training framework that extends the single-group bi-level architecture to enable coordinated policy optimization across simultaneously competing government-household hierarchies. We have also built a robust taxation simulation environment to validate our proposed framework. Through ablation studies on two on-policy MARL algorithms, we assess the robustness, scalability, and convergence of the method across two-group and three-group configurations. Our empirical results demonstrate that MHG effectively simulates realistic multi-group taxation games and that our MARL training framework efficiently optimizes policies, achieving a balance between social welfare and equality.

The main contributions are summarized as follows:

- **A Hierarchical Multi-group Game Formulation:** We propose a novel hybrid game framework for multi-group interactions. Specifically, intra-group cooperation is modeled as a vertical leader-follower game, whereas inter-group competition is formulated as a horizontal noncooperative game. It enables the unified representation of hierarchical cooperation and competitive dynamics.
- **A Dynamic Multi-Group Learning Framework:** We propose a on-policy bi-level MARL framework for the hybrid game. The framework leverages heterogeneous action update frequencies to accommodate the hybrid game structure between governments and households. A *Curriculum Learning* (CL) strategy progressively introduces inter-group competition, allowing agents to first master intra-group dynamics before adapting to cross-group rivalry. A *Closed-Loop Sequential Update* (SU) scheme further supports competition modeling in dynamic repeat game.
- **A Multi-Group Taxation Simulation Environment:** We build a tax game simulation environment based on a classical economic model for experimental validation. Specifically, intra-group dynamics among governments, households, firms, and banks are modeled via the Bewley-Aiyagari framework. Inter-group competition among governments is captured through the Zodrow-Mieszkowski model. Together, they reproduce the strategic complexity of simultaneous government-household and government-government interactions.

The simulation code is available at <https://github.com/zhejing672/MTHG>.

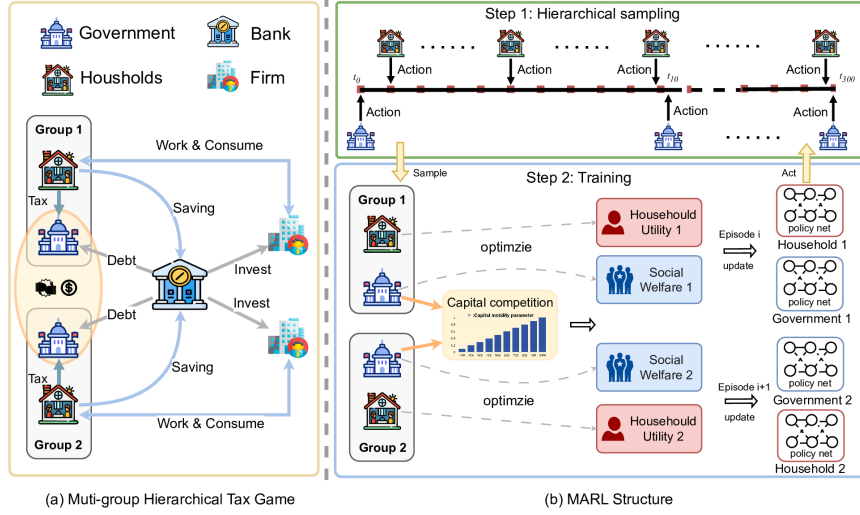

Figure 1: Framework overview. (a): Economic activities among the government, the firm, the financial intermediary, and households. (b): On-policy MARL training process under a bi-level architecture. The sampling stage employs a hierarchical action strategy, where the government updates $a_{g,t}$ every 10 steps, while households update $a_{h,t}$ at each step. The training stage incorporates the curriculum parameter ϕ for reward calculation and employs a sequential mechanism, updating Group 1 and Group 2 at epochs i and $i + 1$, respectively.

2 Related work

2.1 Classic tax models in economics

Taxation has been widely studied in public finance. Early works primarily adopt a normative perspective where the government acts as a social planner and optimizes welfare under household responses. Classical optimal taxation theory models household labor supply and consumption as reaction functions to tax policies, typically within static or single-level optimization frameworks [21, 3]. While these models provide important theoretical insights, they do not explicitly account for strategic interactions among decision-making entities. Subsequent research transitioned toward game-theoretic formulations to capture the strategic interplay between governments and households, typically characterizing taxation as a leader-follower (Stackelberg) game. A significant advancement in this lineage is the integration of the Bewley-Aiyagari framework [1, 2], which enables modeling the responses of heterogeneous households to tax policies under idiosyncratic risk and incomplete markets. To address fiscal competition across regions or countries, tax competition have been extensively studied where multiple governments strategically set tax rates within a non-cooperative game framework [25, 17]. Seminal works, such as the Zodrow–Mieszkowski [30] model, formalize inter-jurisdictional tax competition and highlight key economic phenomena, including fiscal externalities, tax base mobility, and strategic interdependence among governments.

2.2 Game theory in economic analysis

Game theory provides the fundamental mathematical formalism for analyzing strategic interactions in taxation and fiscal policy models [12]. To capture the hybrid nature of modern taxation systems, existing studies typically employ different game-theoretic formulations to model interactions with asymmetric and symmetric strategic power. For instance, leader-follower (Stackelberg) games [24] are commonly adopted when capturing the asymmetric interactions between governments and households. Here, the government acts as the leader by setting tax policies while anticipating households' reaction functions like adjustments in consumption and labor supply. The resulting bi-level structure provides a principled way to analyze how fiscal policies shape individual behavior [9]. By contrast, interactions

among multiple governments are often characterized by relatively symmetric strategic power and are modeled as non-cooperative games. Such characterization is widely used to study strategic competition among jurisdictions and to explain phenomena such as the failure of coordination and the emergence of competitive tax policies. While game theory provides powerful insights, seeking equilibrium solutions for large heterogeneous agents with high-dimensional state spaces becomes analytically intractable. This necessitates the applications of computational methods such as MARL.

2.3 Multi-agent reinforcement learning in economic system

Multi-Agent Reinforcement Learning (MARL) offers a powerful computational framework for addressing complex decision-making problems in multi-agent environments. Over the years, MARL has evolved into a variety of successful algorithms, including off-policy MADDPG [18], on-policy IPPO [11], and MAPPO [26]. To achieve stable and effective optimization in settings with heterogeneous agents, Heterogeneous-Agent Reinforcement Learning (HARL) approaches—such as HAPPO and HATRPO [29]—have been developed, explicitly accounting for agent-specific policy representations and gradient updates.

In economic simulations, multi-agent reinforcement learning (MARL) has demonstrated considerable promise for modeling strategic interactions among economic agents [22, 23, 14, 8]. For instance, Brero et al. [6] formulated economic decision-making as a Stackelberg game and employed reinforcement learning to optimize economic outcomes. Frameworks such as the AI Economist [28] and the RBC-based model [10] further leveraged reinforcement learning to capture bi-level interactions between policymakers and economic agents. Building on these efforts, TaxAI [19] extended RL-based economic simulation to large-scale heterogeneous agent settings. More recently, Mi et al. [20] further incorporated dynamic game structures into macroeconomic policy learning, enabling the study of long-term feedback between government policies and adaptive household behaviors. However, these approaches primarily focus on intra-group interactions within a single government-household system. In contrast, our MGH framework not only models such intra-group dynamics but also incorporates strategic competition across multiple government-household systems, providing a broader perspective for investigating complex economic simulations.

3 Hierarchical multi-group tax game

We propose the multi-group tax game as a framework to describe the complex phenomenon in economic society. Figure 1(a) illustrates its structure, showing hierarchical interactions among four entities: households, governments, firms, and banks. Within each group, the government acts as the *high-level agent* and optimizes social welfare (measured by GDP and the Gini coefficient) through tax policy adjustments. Households serve as *low-level agents* and maximize individual utilities by choosing labor supply and consumption. Firms and banks act as *intermediary institutions* and enable the conversion and circulation of labor and capital. Across groups, governments compete for mobile capital to advance their own economic interests. Thus, we have two types of strategic interactions. The *intra-group interaction* models the government-household hierarchy via a leader-follower game grounded in the Bewley-Aiyagari framework. The *inter-group interaction* captures tax competition among governments through a noncooperative game based on the Zodrow-Mieszkowski model. Full mathematical details are provided in Appendices A-B.

3.1 Intra-group leader-follower game

Following the notations in Appendix A, we introduce the actions and objectives of four entities, respectively.

Households A household has two actions: saving ratio p_t and working hour h_t at time t . We also denote i_t , a_t , and c_t as the household’s income, wealth, and consumption, respectively. Under the assumption of the fixed consumption tax rate (10), the household’s consumption c_t can be represented in terms of the saving ratio p_t by

$$c_t = \frac{1 - p_t}{1 + \tau_s} [i_t - T_{\text{inc}}(i_t) + a_t - T_{\text{ast}}(a_t)], \quad (1)$$

where $T_{\text{inc}}(\cdot)$ and $T_{\text{ast}}(\cdot)$ are income and asset tax functions, respectively. Based on the working-spending dynamics in (1) and (6)-(9), each household seeks to optimize her objective function given

by

$$\max_{p_t, h_t} \mathbb{E} \sum_{t=0}^T \beta^t \left(\frac{(c_t)^{1-\theta}}{1-\theta} - \frac{(h_t)^{1+\gamma}}{1+\gamma} \right), \quad (2)$$

where $T > 0$ is the decision horizon and $\beta \in [0, 1]$ is the discounted factor. The objective captures the household's utility (or "happiness"), which increases with consumption c_t and decreases with labor effort h_t . The two terms are shaped by risk preferences, with $\theta > 0$ and $\gamma > 0$ representing the coefficients of relative risk aversion (CRRA) for consumption and disutility of labor, respectively.

When there are M households present, they are independent and heterogeneous, distinguished by their individual productivity levels (5) and financial states. Each household evolves autonomously according to the aforementioned working-spending dynamics. Although decisions are made independently, their aggregate behaviors jointly influence the wage rate and, consequently, the government's tax policy. For instance, the wage rate defined in (15) is determined by the joint labor supply of all households.

Government The government interacts with households through two adjustable policy instruments: tax policies and the spending ratio η_t . Regarding taxation, we consider three types of taxes: consumption, income, and asset taxes. Based on the tax policy selection in (10)-(12), the government chooses a fixed consumption tax rate τ_s , the income tax parameter $\theta_i := (\tau_i, \xi_i)$, and the asset tax parameter $\theta_a := (\tau_a, \xi_a)$. In addition to taxation, the government determines the scale of its fiscal expenditure to support public spending, defined by $\eta_t = \frac{G_t}{Y_t}$. Here, G_t and Y_t are the government's social spending and the total production. The debt dynamics in (13) explicitly links the government's policy choices (captured by θ_i, θ_a , and η_t) to its fiscal state trajectory.

Based on the production function (14) and the debt dynamics (13), the government seeks to optimize a social welfare objective that emphasizes both economic efficiency and equality. Specifically, it maximizes the expected cumulative product of production and the inverse Gini index over the planning horizon:

$$\max_{\theta_i, \theta_a, \eta_t} \mathbb{E} \sum_{t=0}^T \beta^t \log(Y_t) \cdot \left(1 - \text{Gini}(\{i_t^j\}, \{a_t^j\}) \right) \quad (3)$$

where Y_{-1} is given as the initial baseline production output and $\text{Gini}(\{i_t^j\}, \{a_t^j\})$ denotes the joint Gini index over all households' income and asset distributions. The objective balances two competing dimensions of social welfare. The term $1 - \text{Gini} \in [0, 1]$ measures equality, attaining 1 under perfect equality and approaching 0 under maximal concentration. The term $\log(Y_t)$ captures economic efficiency via aggregate output. Their product trades off efficiency and equality within a single metric. The logarithmic transformation serves two roles. First, it reflects diminishing marginal welfare from output, preventing large values of Y_t from dominating the objective. Second, it improves numerical stability by reducing the scale of the reward signal and mitigating gradient variance.

3.2 Inter-group competition game

We model inter-group interaction as a strategic competition among governments. This is motivated by the observation that cross-group dynamics are primarily driven by group leaders, who both interact most directly with one another and exert the greatest influence over their respective followers. Consequently, leader-leader interactions dominate the cross-group dynamics.

The competition is characterized through *capital regulation*. Each government can strategically set a capital tax rate $\tau_t^{(n)}$ to either attract or repel mobile capital and further influence its domestic capital stock and objective in (3). Let the superscript (n) denote the quantities related to the n -th group. Based on the law of motion for capital detailed in Appendix B, the real capital in group n is given by

$$\begin{aligned}
K_{t+1}^{(n),\text{real}} &= \underbrace{K_{t+1}^{(n)}}_{\text{Internal Accumulation}} + \underbrace{\Delta K_t^{(n),\text{flow}}}_{\text{External Competition}} \\
&= r_{\text{interest}} K_t^{(n)} + (1 + r_{\text{interest}}) \left(B_t^n - \sum_{j=1}^{M^{(n)}} a_t^{j,(n)} \right) + \sum_{j=1}^{M^{(n)}} a_{t+1}^{j,(n)} - B_{t+1}^{(n)} - \phi \left(\tau_t^{(n)} - \bar{\tau}_t \right) K_t^{(n)},
\end{aligned} \tag{4}$$

where $\bar{\tau}_t$ is the average capital tax rate across all groups at time t . All other variables are extended to the n -th group analogously and remain their original economic interpretations.

4 Multi-group bi-level learning framework

4.1 Environment setting

To interface with standard MARL methods, we express the model in the form of a partially observable Markov game, defined by the tuple $\langle \mathcal{N}, \mathcal{S}, \mathcal{O}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \beta \rangle$. This representation is adopted for notational compatibility rather than as an additional modeling assumption. Here, $\mathcal{N}$ denotes the set of agents and $\mathcal{S}$ the state space. Each agent $i \in \mathcal{N}$ has observation and action spaces $\mathcal{O}_i$ and $\mathcal{A}_i$, with joint spaces $\mathcal{O} = \prod_i \mathcal{O}_i$ and $\mathcal{A} = \prod_i \mathcal{A}_i$. The reward function is $\mathcal{R} = \{R_i(s, a)\}_{i \in \mathcal{N}}$, where $R_i(s, a)$ is the reward to agent i under state s and joint action a . The transition kernel $\mathcal{P}$ governs the system dynamics, and $\beta \in [0, 1]$ is the discount factor. We partition $|\mathcal{N}|$ agents to N groups. Each group consists of one government and $N^{(n)} - 1$ households, $n = 1, \dots, N$. Since all governments share a common observation and action spaces, and similarly for households, we omit group indices when defining these spaces for simplicity.

Action space A government agent's action at time t is $a_{\text{gov},t} := (\theta_i, \theta_a, \eta_t, \tau_t)$, which contains tax parameters, social spending ratio, and capital tax rate. Each household j in group n takes action $a_{\text{hh},t}^j := (p_t^j, h_t^j)$, representing its saving ratio and working hours.

Observation space In practice, it is unrealistic to assume that a government can observe all individual household states. Following [19], we approximate household-level information using aggregate statistics. Specifically, at time t , households are partitioned into the top 10% richest and 50% poorest, and we compute their averaged income $(\bar{i}_t^{\text{top}}, \bar{i}_t^{\text{btm}})$, averaged asset $(\bar{a}_t^{\text{top}}, \bar{a}_t^{\text{btm}})$, and averaged productivity $(\bar{e}_t^{\text{top}}, \bar{e}_t^{\text{btm}})$. These aggregates, together with the current wage rate w_t form the core of the government's observation. Moreover, due to inter-group competition, each government also observes the previous-period actions of rival governments, denoted $a_{g,t-1}^{(-n)}$, where the superscript $(-n)$ indicates all groups except group n . The observation for a government in group n at time t is

$$o_{\text{gov},t} = \left(w_t, \bar{i}_t^{\text{top}}, \bar{i}_t^{\text{btm}}, \bar{a}_t^{\text{top}}, \bar{a}_t^{\text{btm}}, \bar{e}_t^{\text{top}}, \bar{e}_t^{\text{btm}}, a_{g,t-1}^{(n-1)} \right).$$

Households, observe both their own financial state and the same aggregated group statistics (macro-level trends). For household j in group n , the observation is

$$o_{\text{hh},t}^j = \left(w_t, i_t^j, a_t^j, e_t^j, \bar{i}_t^{\text{top}}, \bar{i}_t^{\text{btm}}, \bar{a}_t^{\text{top}}, \bar{a}_t^{\text{btm}}, \bar{e}_t^{\text{top}}, \bar{e}_t^{\text{btm}} \right).$$

Interactive Dynamics we describe how the system evolves at each time step t . Within each group, the government acts as the leader: it observes aggregate household statistics $o_{\text{gov},t}$ and sets policy parameters $(\theta_i, \theta_a, \eta_t)$ with fiscal dynamics governed by (13). Households, as followers, observe their individual financial state (i_t, a_t, e_t) together with the current government policy $a_{\text{gov},t}$, and choose saving and labor decisions (p_t, h_t) . Across groups, in addition to $o_{\text{gov},t}$, each government observes the previous-period policies of other governments $a_{\text{gov},t-1}^{(-n)}$ and adjusts its capital tax rate τ_t . These decisions influence the allocation of mobile capital via the flow rule (17), thereby affecting production and household dynamics in all groups. This coupling induces strategic interdependence among governments and links the evolution of otherwise separate groups.

4.2 Learning framework design

Introducing inter-group competition induces a nested game structure and significantly complicates the game dynamics. In particular, the capital tax rate τ affects the intra-group capital stock, which in turn influences wage rate w_t . Households respond by adjusting their labor supply, which further impacts capital accumulation and, consequently, each government’s competitiveness in attracting mobile capital. Such interdependency makes the environment highly non-stationary and difficult to handle with standard methods. Conventional MARL approaches typically struggle with structured interactions of this kind, while bi-level MARL methods face challenges in simultaneously capturing both intra- and inter-group dependencies. As a result, directly applying these methods often leads to unstable training.

We observe that the primary source of difficulty arises from inter-group competition. As group leaders, governments must not only manage intra-group dynamics to maintain domestic economic stability but also anticipate the strategies of competing governments to attract capital inflows. To address this, we first introduce a *hierarchical sampling* strategy that supports the leader-follower learning structure within each group. Next, we propose a *curriculum learning* scheme that gradually increases the strength of inter-group competition, allowing governments to first learn stable intra-group policies before adapting to strategic competition. In addition, to mitigate non-stationarity, we propose a *closed-loop sequential update* mechanism at the episode level. This mechanism enables governments to incrementally adapt to opponents’ behaviors in a more stable and structured manner.

Details of all components are elaborated in the following sections.

4.2.1 Hierarchical sampling

Within each group, the government-household interaction follows a leader-follower structure, where the government sets policy by anticipating household responses. In standard MARL training, however, both levels update at the same temporal resolution, making it difficult for the government to form stable estimates of household behavior and weakening the intended hierarchy.

To address this, we introduce a *hierarchical sampling* strategy that separates the time scales of government and household decisions. Households operate at a fine scale, sampling observations and acting at every time step, while the government updates its policy at a coarser interval of $n_{\text{gov}} > 1$ steps. During each government decision interval, the policy remains fixed, allowing household responses to evolve and reveal stable behavioral patterns. Data are collected according to this schedule for each group. This design enables the government to better anticipate household responses and reinforces the leader-follower learning structure.

4.2.2 Curriculum learning

Curriculum learning mechanism gradually introduces inter-group competition into the intra-group leader-follower game. It controls the intensity of inter-group competition through the capital mobility parameter ϕ , defined as

$$\phi = \min(0.001 \times \text{episode}, 1).$$

At early training stages, ϕ is close to zero, implying limited capital mobility between groups and effectively decoupling groups, allowing the model to focus primarily on the intra-group leader-follower game. As training progresses and the intra-group strategies largely stable, ϕ gradually increases, strengthening inter-group competition and encouraging governments to adapt their policies in response to rivals.

In implementation, we alternate between intra-group and inter-group updates. For each episode, we first suppress inter-group competition and train governments and households within each group under the leader-follower structure. Next, we fix the learned intra-group policies, set ϕ according to the curriculum, and update the inter-group policy. This alternating procedure stabilizes training while enabling gradual adaptation to competition.

4.2.3 Closed-loop sequential update

Conventional MARL methods update agents simultaneously at each training episode, which makes it difficult for agents to identify and adapt to others’ behavioral patterns. In contrast, the *closed-loop*

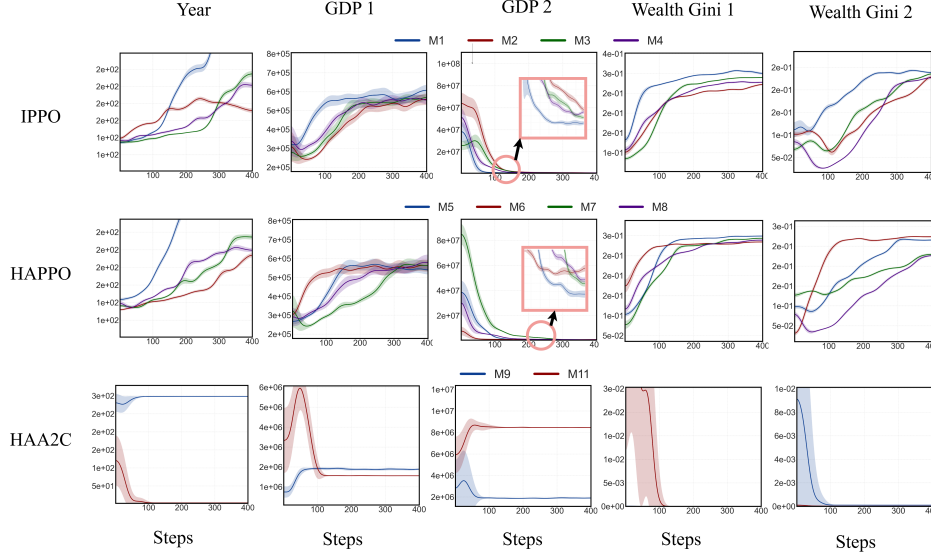

Figure 2: Trajectory of economic indicators for different groups throughout the training process.

sequential update mechanism (Figure 6) updates only one group of agents per training episode while keeping others unchanged. Different groups are updated sequentially according to a fixed order.

This design is inspired by dynamic game theory. By holding non-updated groups stationary, each update step provides a stable behavioral reference for learning. As a result, agents can better infer and respond to the evolving patterns of other agents, thereby improving training stability and facilitating the emergence of cooperative behaviors.

4.2.4 Training Procedure

Figure 1(b) illustrates the overall training framework, and the full details are provided in Appendix E. The method integrates three components: hierarchical sampling, curriculum learning, and closed-loop sequential updates. Hierarchical sampling enforces the leader-follower structure within each group by operating governments and households at different time scales. Curriculum learning gradually increases the strength of inter-group competition via ϕ , enabling policies to stabilize before adapting to competition. Closed-loop sequential updates further improve stability by updating one group at a time while keeping others fixed.

5 Experiments and analysis

We conduct two sets of experiments: an ablation study and a scalability evaluation. Performance is assessed using three economic indicators. The interaction horizon (in years) reflects the duration of inter-group competition and serves as a measure of algorithmic robustness. Simulations terminate if any group’s capital is depleted. GDP measures the average per-step economic output of each group. The Gini index quantifies household wealth inequality, with values closer to zero indicating more equitable distributions.

5.1 Ablation study

We conduct a comprehensive ablation study to evaluate the effectiveness of the proposed learning methods. All reported results are averaged over 20 independent random seeds to ensure statistical reliability and mitigate the effect of randomness. We established a baseline using the Independent PPO (IPPO) algorithm and systematically incorporated our key components, *Curriculum Learning* (CL) and *Closed-Loop Sequential Update* (SU), to the learning process.

Table 1: Detailed ablation study of different components. **CL** denotes Curriculum Learning, and **SU** denotes Sequential Update.

Model ID	Intra-group	Inter-group	CL	SU
M1	IPPO	IPPO	✓	✓
M2	IPPO	IPPO	✓	–
M3	IPPO	IPPO	–	✓
M4	IPPO	IPPO	–	–
M5	HAPPO	IPPO	✓	✓
M6	HAPPO	IPPO	✓	–
M7	HAPPO	IPPO	–	✓
M8	HAPPO	IPPO	–	–
M9	HAA2C	IA2C	✓	✓
M10	HAA2C	IA2C	✓	–
M11	HAA2C	IA2C	–	✓
M12	HAA2C	IA2C	–	–

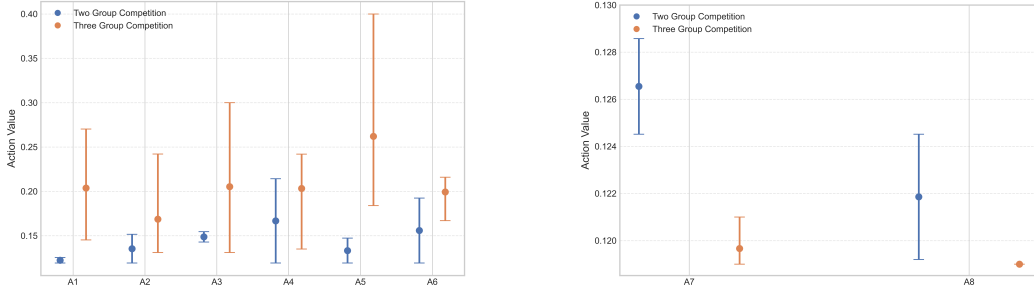

Figure 3: Groups action error bars under different settings

Table 1 summarizes the experimental configurations and results. **M1** integrates both modules into the IPPO framework. **M2** and **M3** introduce Curriculum Learning and Sequential Update individually, allowing us to isolate the impact of stabilizing training and modeling leader-follower dependencies, respectively. **M4** represents the vanilla IPPO baseline without any enhancements. Furthermore, to demonstrate the efficacy of the heterogeneous agent modeling, we extend the evaluation to HAPPO-based architectures (**M5–M8**) and HAA2C-based architectures (**M9–M12**) for intra-group optimization. To ensure a fair comparison and isolate the first-update advantage modeling from the inherent algorithmic advantages of HAPPO and HAA2C, the inter-group optimization is kept consistent across all models, using IPPO and IA2C respectively.

Table 2 reports the economic indicators of different models under various experimental settings.

Inter-group Competition Analysis By comparing M3 vs. M4 and M7 vs. M8, we observe that the introduction of SU significantly reduces the performance gap between competing groups. Specifically, the GDP differences between groups are reduced by 1.1 and 0.4, respectively. This result suggests that sequential policy updates enable agents to better capture and adapt to the behavioral patterns of their opponents, leading to more symmetric competitive outcomes. In terms of competition duration, M1 and M2 demonstrate that CL substantially prolongs the game horizon, with increases of 75.8 and 125.7 years, respectively. This indicates that governments are able to learn more effective taxation strategies that stabilize intra-group capital dynamics, thereby delaying market collapse and sustaining long-term competition among groups.

From the perspective of intra-group dynamics, comparisons between M3 vs. M4 and M7 vs. M8 reveal that SU leads to an increase in the wealth Gini index by approximately 0.4–1.3. This suggests that intensified inter-group competition amplifies wealth inequality within groups, as agents adapt

their strategies to external competitive pressures. A similar trend is observed when CL is applied. While CL improves overall economic efficiency, it also alters household-level wealth distribution, indicating that governmental taxation policies directly influence intra-group inequality. Additionally, compare M1 with baseline M4, our method avoids catastrophic game termination, extends the duration by 60.92%, yields more sustainable and robust tax policies, and reduces GDP disparities among governments by 44.12%. These findings are consistent with the hierarchical structure in leader-follower games, where the government’s first-mover advantage shapes the strategic responses of households and ultimately affects wealth allocation.

Table 2: The economic indicators of ablation experiment

Baselines group #	Years	GDP(10^5)		Wealth Gini(%)	
		1	2	1	2
M1	269.4	6.1	6.9	29.9	23.8
M2	193.6	5.6	8.8	27.2	22.9
M3	214.6	5.7	7.7	29.0	23.6
M4	200.1	5.5	8.6	27.7	22.7
M5	289.2	5.3	6.6	29.9	26.5
M6	173.5	5.5	9.7	28.4	27.4
M7	214.7	5.7	7.9	29.3	23.0
M8	201.4	5.8	8.4	28.9	22.6
M9	300	18.8	18.9	0	0
M10	-	-	-	-	-
M11	0	16.3	85.3	0	0
M12	-	-	-	-	-

Table 3: Group average action

	A1	A2	A3	A4	A5	A6	A7	A8
M1	0.13	0.14	0.15	0.17	0.13	0.16	0.13	0.12
M5	0.12	0.12	0.13	0.12	0.14	0.17	0.12	0.12
M9	0.88	0.88	0.88	0.88	0.47	0.88	0.50	0.88
M11	0.88	0.88	0.88	0.88	0.47	0.88	0.50	0.88

Figure 2 Experimental results demonstrate that the combination of our proposed curriculum strategy and sequential decision-making mechanism yields the most robust performance across all metrics.

5.2 Scalability and robustness analysis

In this section, we increase the number of groups to three in order to examine how governmental policies evolve under more complex competitive environments and to evaluate the robustness of the proposed framework. Table 4 summarizes the economic outcomes of models M1 and M5 in the three-group setting. Compared with the two-group experiments, M1 continues to exhibit strong performance, with the competition duration increasing by 17.6 years. However, in terms of GDP, intensified external competition leads to a reduction in economic output. Interestingly, relative to the two-group setting, the wealth Gini coefficient decreases while the income Gini coefficient increases. Figure 3 show that heightened competition exacerbates income inequality, whereas governments mitigate wealth inequality through redistributive policies such as social welfare transfers.

Overall, IPPO exhibits the best performance across the three groups optimization scenarios. Consequently, Fig. 3 illustrates the action policies optimized based on M1. Here, A1-A6 represent the six dimensions of the government’s action space, while A7 and A8 denote the household actions. As observed in Fig. 3b, an increase in the number of game groups has a negligible impact on household decision-making. Instead, it primarily influences government strategies, manifested by an increase in tax rates and a widening divergence in tax policies among different governments.

Baselines	Years	GDP(10^5)			Wealth Gini(%)			Incom Gini(%)		
		1	2	3	1	2	3	1	2	3
M1	287.0	5.7	6.1	5.5	9.1	27.2	20.7	39.2	44.3	43.8
M5	196.3	7.9	5.4	7.2	24.4	22.5	19.0	42.7	42.5	41.9

Discussion

In this study, we constructed a multi-group hierarchical taxation game simulation environment and employed on-policy MARL algorithms for optimization. To effectively capture the dynamic game processes, we integrated CL and SU strategies into the training framework. Experimental results demonstrate that our approach significantly enhances the optimization capability of the model. Quantitatively, compared to the initial baseline, our method extends the simulation duration by 60.92%, leading to more sustainable and robust tax policies. Furthermore, it reduces the GDP disparity among governments by 44.12%. Despite these promising results, several limitations remain. Currently, our MARL framework is optimized for a limited number of groups (up to three), and the simulation assumes a static household population. Consequently, there is substantial room for future optimization to scale up the simulation to accommodate a larger number of groups and agents.

A Bewley-Aiyagari model

The Bewley-Aiyagari model describes a minimal economic circulation system that includes four entities: household, government, firm, and financial intermediary.

Households In the economic system, a household get paid by working and spend money by consumption, forming a working-spending dynamics that powers economic circulation. We define i_t , a_t , and c_t as the income, wealth, and consumption of a household at time t , which represents the financial state of a household. We also denote h_t and w_t as the working hour and the wage rate, respectively. To capture heterogeneous characters of different households, we introduce productivity level e_t , which denote the household's working efficiency. We assume e_t follows a AR(1) process, taking a value of either super-star or a normal state, given by

$$\log e_{t+1} = \rho_e \log e_t + \sigma_e u_t, \quad (5)$$

where $u_t \sim \mathcal{N}(0, 1)$ denotes a standard normal shock, and $\rho_e \geq 0, \sigma_e \geq 0$ are the persistence and the volatility of the shock. Let r_{interest} be the interest rate. A household's income in time t can be given by

$$i_t = w_t h_t e_t + r_{\text{interest}} a_t, \quad (6)$$

We consider three types of taxation policies in the model, which are income, asset, consumption taxes, denoted by $T_{\text{inc}}(i_t)$, $T_{\text{ast}}(a_t)$, and $T_{\text{cons}}(c_t)$, respectively. Note that these tax policies are adjustable functions of a household's financial status. Based on the income, consumption, and tax, we can derive the wealth accumulation relation as

$$a_{t+1} = i_t - T_{\text{inc}}(i_t) + a_t - T_{\text{ast}}(a_t) - c_t - T_{\text{cons}}(c_t). \quad (7)$$

Let p_t denote the household's saving ratio to simplify the complex household's working-spending dynamics in (5)-(7) and training, which is given by

$$p_t = \frac{a_{t+1}}{i_t - T_{\text{inc}}(i_t) + a_t - T_{\text{ast}}(a_t)}. \quad (8)$$

This simplifies the wealth evolution (7) to

$$a_{t+1} = p_t (i_t - T_{\text{inc}}(i_t) + a_t - T_{\text{ast}}(a_t)). \quad (9)$$

Government A government is responsible for taxing, social spending, and capital regulation. For taxation, we consider three types of tax policies: consumption, income, and asset taxes. In practice, the consumption tax can be modeled with a fixed rate τ_s [7], i.e.,

$$T_{\text{cons}}(c_t) = \tau_s c_t. \quad (10)$$

The income tax $T_{\text{inc}}(i_t)$ and the asset tax $T_{\text{ast}}(a_t)$ are widely adopted by the nonlinear HSV [5, 13], given by

$$T_{\text{inc}}(i_t) = i_t - \frac{1 - \tau_i}{1 - \xi_i} (i_t)^{1 - \xi_i}, \quad (11)$$

$$T_{\text{ast}}(a_t) = a_t - \frac{1 - \tau_a}{1 - \xi_a} (a_t)^{1 - \xi_a}. \quad (12)$$

Here, τ_i and ξ_i control the average level and the slop of the marginal income tax; similarly, τ_a and ξ_a determine the average level and the slop of the asset tax.

In its role of social spending, the government may issue debt into the economic system and must service this debt by paying interest at rate r_{interest} . Let G_t and B_t denote the government's social spending and debt at time t , respectively, which together characterize its fiscal state. Assuming there are M households paying taxes. With a slight abuse of notation, we use superscript to index households and denote i_t^j , a_t^j , c_t^j as the j -th household's income, wealth, and consumption at time t . The government's debt evolves according to

$$B_{t+1} = (1 + r_{\text{interest}})B_t + G_t - \sum_{j=1}^M (T_{\text{inc}}(i_t^j) + T_{\text{ast}}(a_t^j) + T_{\text{cons}}(c_t^j)). \quad (13)$$

When introducing the spending ratio $\eta_t = \frac{G_t}{Y_t}$, the social spending G_t can be represented by $\eta_t Y_t = \eta_t K_t^\alpha L_t^{1-\alpha}$ using Cobb-Douglas production function (14), which can be used to further simplify the debt dynamics (13).

Capital regulation arises in multi-group settings, where governments compete for mobile capital to enhance their economic welfare. This inter-group strategic behavior is captured through tax competition dynamics and is formally modeled in Appendix B.

Firm A firm abstracts all production units in the economic circulation. It hires households to conduct production and pays wages to households. We use the widely adopted Cobb-Douglas production function to summarize the production process:

$$Y_t = K_t^\alpha L_t^{1-\alpha} \quad (14)$$

where K_t and L_t are capital and labors used for production and $\alpha \in (0, 1)$ is the capital elasticity. Suppose there are M households participating the production, we have $L_t = \sum_{j=1}^M h_t^j e_t^j$, representing the total effective labor supply. Using the assumption that the firm takes the marginal income from labor as the households' wage rate w_t (i.e., the market-clearing condition), we obtain

$$w_t = \frac{\partial Y_t}{\partial L_t} = (1 - \alpha) \left(\frac{K_t}{L_t} \right)^\alpha = (1 - \alpha) \frac{K_t^\alpha}{\left(\sum_{j=1}^M e_t^j h_t^j \right)^\alpha}. \quad (15)$$

It shows that all households face the same wage rate, which is endogenously determined by their collective labor supply and the available capital stock K_t .

Financial intermediary A financial intermediary abstracts institutions such as banks that collect households' savings and allocate these funds to productive capital and government bonds. This allocation determines the market's available capital for production in the subsequent period. Assuming M households deposit their savings into the intermediary, the evolution of aggregate capital and government debt satisfies

$$K_{t+1} + B_{t+1} - \sum_{j=1}^M a_{t+1}^j = r_{\text{interest}} K_t + (1 + r_{\text{interest}}) \left(B_t - \sum_{j=1}^M a_t^j \right). \quad (16)$$

Here, K_t denotes the capital stock held by the intermediary at time t , which corresponds to the total capital available to firms for production in (14). B_t represents the government debt, and a_t^j denotes the asset of household j at time t . This equation balances the intermediary's portfolio across periods and accounts for returns on capital and interest payments on government debt.

B Zodrow-Mieszkowski dynamics

In a multi-group setting with N governments, capital is treated as an imperfectly mobile factor of production. Investors observe the effective capital tax rates across all regions and reallocate capital to maximize after-tax returns. This process implies that capital tends to migrate from high-tax jurisdictions to low-tax ones, a phenomenon often referred to as the "Race to the Bottom."

We use superscript to denote the group index and let $K_t^{(n)}$ denote the capital stock in group n at time t . The dynamics of capital flow are governed by the deviation of the local capital tax rate $\tau_t^{(n)}$ from the average tax rate of all groups $\bar{\tau}_t$. The law of motion for capital, adjusted for these flows, is formulated as:

$$\Delta K_t^{(n), \text{flow}} = -\phi \cdot (\tau_t^{(n)} - \bar{\tau}_t) \cdot K_t^{(n)}, \quad (17)$$

where $\bar{\tau}_t = \frac{1}{N} \sum_{n=1}^N \tau_t^{(n)}$ represents the market average tax rate. It is a classic inter-jurisdictional capital reallocation from the Zodrow-Mieszkowski tax competition model, widely adopted in the fiscal competition literature. Here, $\bar{\tau}_t = \frac{1}{N} \sum_{n=1}^N \tau_t^{(n)}$ represents the market average tax rate. It captures the standard "Race to the Bottom" phenomenon: capital flows out of high-tax jurisdictions and into low-tax ones proportionally to the tax differential $(\tau_t^{(n)} - \bar{\tau}_t)$ and the current capital stock $K_t^{(n)}$. The parameter $\phi > 0$ controls the intensity of capital mobility, and is treated as a fixed constant in standard models.

Incorporating this dynamic into the standard accumulation process, the aggregate capital for jurisdiction i at the next time step is updated by:

$$K_{t+1}^{(n), \text{real}} = K_{t+1}^{(n)} + \Delta K_t^{(n), \text{flow}}, \quad (18)$$

where $K_{t+1}^{(n), \text{real}}$ represents the real available capital accumulation. This mechanism forces governments to strategically lower tax rates to attract or retain the tax base, often at the expense of public good provision or fiscal balance.

C Simulation settings

C.1 Termination condition

The simulation will terminate the current episode if the following conditions are met:

- If the maximum number of steps in an episode is reached.
- if any group of the capital for production be zero.

C.2 Hyperparameters

We summarize the hyperparameters of various baseline MARL algorithms in Tables 5-6.

Table 5: Hyperparameters of HAPPO, IPPO

Hyperparameter	value	Hyperparameter	value	Hyperparameters	Value
Eval episode	10	Optimizer	Adam	Episode length	300
Gamma	0.95	Optim eps	$1e - 5$	Hidden	64
Gain	0.01	Activation	ReLU	Training threads	10
Actor network	MLP	Rollout threads	1	Critic lr	$5e - 3$
Actor lr	$3e - 5$	Gov actor lr	$3e - 5$	Gov critic lr	$3e - 5$

Table 6: Hyperparameters of HAA2C

Hyperparameter	value	Hyperparameter	value	Hyperparameters	Value
Eval episode	10	Optimizer	Adam	Episode length	300
Gamma	0.95	Optim eps	$1e - 5$	Hidden	64
Gain	0.01	Activation	ReLU	Training threads	10
Actor network	MLP	Rollout threads	1	Critic lr	$3e - 7$
Actor lr	$1e - 7$	Gov actor lr	$1e - 7$	Gov critic lr	$1e - 7$

C.3 Simulation variables

We summarize key variables in the economic simulation in Table 7.

Table 7: Key variables in the economic simulation environment

Variable	Meaning	Variable	Meaning
w_t	Wage rate	e_t	Individual labor productivity levels
h_t	Working hours	a_t	Household's asset (wealth)
a_0	Household's initial asset (wealth)	r_{interest}	Interest rate
i_t	Household's income	N	Number of households
ρ_e	Persistence	u_t	Standard normal shocks
β	Discount factor	θ	Coefficient of relative risk aversion (CRRA)
γ	Inverse Frisch elasticity	τ_s	Consumption tax rate
$T_{\text{inc}}(i_t)$	Income taxes	$T_{\text{ast}}(a_t)$	Asset taxes
τ_i, τ_a	Average level of marginal income and asset tax	ξ_i, ξ_a	Slope of marginal income and asset tax schedule
τ_k	Capital tax	Y_t	Firm's output
K_t	Capital for production	L_t	Labor for production
α	Capital elasticity	G_t	Government social spending
G_t	Government spending	B_t	Government debt

D Additional experiment results

Table 8 and Table 9 present a comparison of macroeconomic indicators and equilibrium policy actions under different numbers of competing groups, respectively. The one-group setting is optimized by TaxAI, a single-group bilevel MARL framework, while the two-group setting is optimized by M1.

Economic policy and macroeconomic relationship analysis As shown in Table 8, the introduction of inter-group competition leads to notable changes in both economic efficiency and equality. In the two-group setting, the GDP of group 1 increases from 5.8×10^5 to 6.1×10^5 , and group 2 achieves an even higher GDP of 6.9×10^5 , suggesting that inter-group competition incentivizes governments to adopt more growth-oriented policies. However, this efficiency gain comes at the cost of higher wealth inequality: the Wealth Gini coefficient of group 1 rises from 21.0% to 29.9%, indicating that competitive pressure may induce governments to prioritize GDP growth over distributional equity.

This observation can be explained through the economic policy. Compared to the two-group setting, the one-group government adopts higher income tax rates (A1–A2), as reflected in Table 9. By the definition of the Gini coefficient, higher and more progressive tax rates contribute to redistributing wealth and thereby reducing wealth inequality. The tax revenues collected are subsequently allocated to public infrastructure investment, as evidenced by the higher A5 value in the one-group setting, indicating a greater proportion of expenditure directed toward public goods. This in turn raises household utility and welfare. Nevertheless, the increased tax burden and elevated public spending suppress private capital accumulation and economic output, which accounts for the lower GDP observed in the one-group setting.

On the necessity of the two-group competition game A6 denotes the capital tax rate, which serves as a key instrument of inter-group capital competition, as governments strategically adjust capital taxation to attract investment and gain a competitive edge over rival groups.

As shown in Table 9, compared to the one-group setting, three-group governments adopt lower income tax rates (A1–A2) and higher asset tax rates (A3–A4). This policy shift increases households’ disposable income and incentivizes greater consumption, which in turn stimulates GDP growth. Meanwhile, the reduction in A5 indicates that inter-group competition leads governments to allocate a smaller proportion of expenditure toward public infrastructure, as competitive pressure shifts the policy focus from public welfare provision toward economic output maximization. Collectively, these policy adjustments drive higher GDP growth under inter-group competition, but simultaneously exacerbate wealth inequality, as evidenced by the higher Gini coefficients observed in the two-group setting in Table 8. Notably, the elevated Gini coefficients in the multi-group setting more closely reflect the wealth disparity observed in real-world societies, suggesting that inter-group competition captures a more realistic dimension of macroeconomic dynamics.

Furthermore, inter-group competition has negligible influence on household actions (A7–A8), which remain stable across both settings. This suggests that household behavior is primarily governed by intra-group dynamics — namely, the Leader-Follower interaction with their own government — and is largely insensitive to the inter-group competitive environment. These findings collectively validate the necessity of explicitly modeling inter-group competition at the government level, as it gives rise to qualitatively different macroeconomic equilibria that are richer and more realistic than those produced by single-group optimization alone.

Table 8: The economic indicators at different group competitions

Baselines Group number #	Years	GDP(10^5)		Wealth Gini(%)	
		1	2	1	2
One Group	300	5.8	/	21.0	/
Two group	269.4	6.1	6.9	29.9	23.8

Figure 4 illustrates the dynamic evolution of agents’ actions during the training process under different reinforcement learning algorithms. Under IPPO-based and HAPPO-based algorithms, the agents’ actions converge to relatively low values. Specifically, A7-A8 denote the households’ consumption rate and labor participation rate, both stabilizing at around 10%, while the government’s tax rate

Table 9: Group average action optimized

	A1	A2	A3	A4	A5	A6	A7	A8
One Group	0.20	0.17	0.14	0.16	0.15	/	0.12	0.12
Two group	0.13	0.14	0.15	0.17	0.13	0.16	0.13	0.12

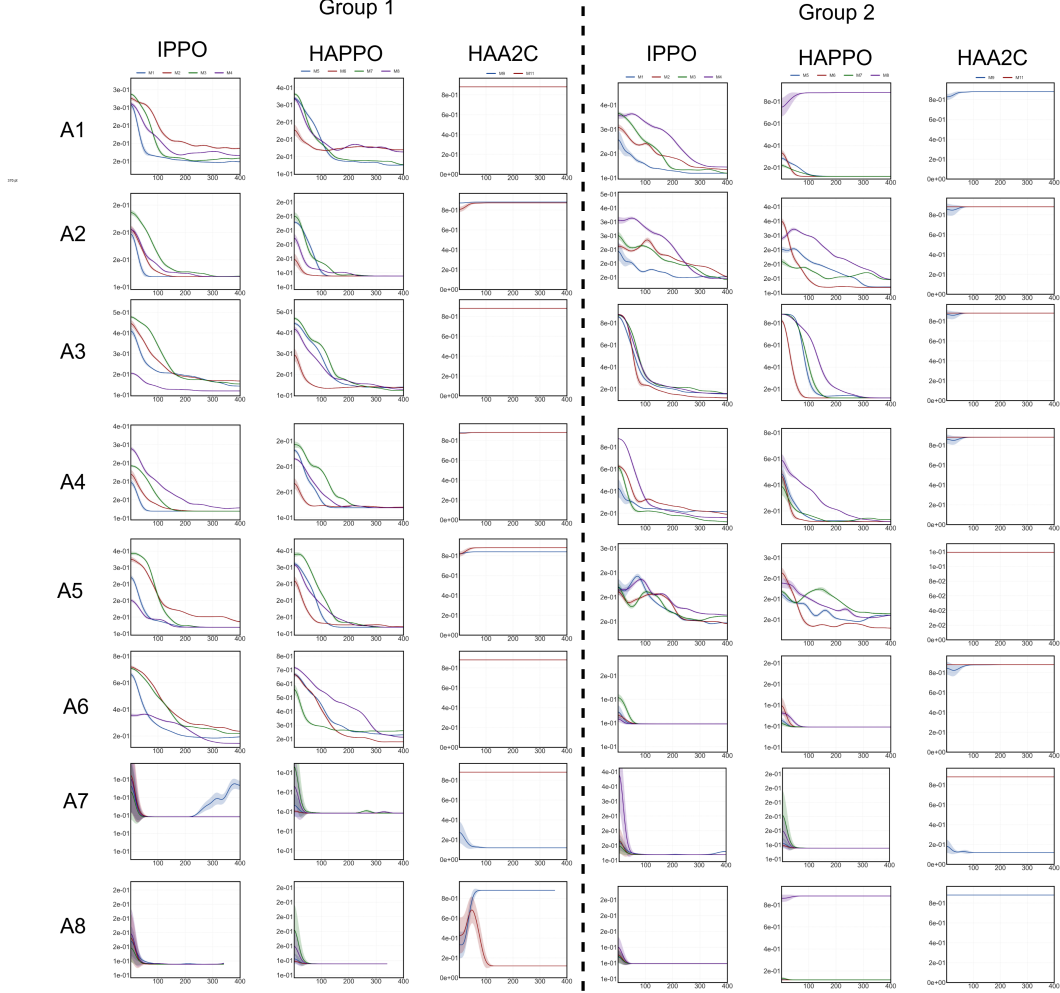

Figure 4: Action trajectories of different agents under various MARL algorithms during training

converges to a similarly low level of approximately 20%. These outcomes are broadly consistent with real-world economic observations.

In contrast, the HAA2C-based model converges to values close to 0.8 for both government and household actions. From a theoretical perspective, this corresponds to a cooperative equilibrium: households exert higher labor effort to boost GDP, while the government redistributes a large proportion of fiscal revenue back to households in the form of social welfare, thereby reducing income inequality as measured by the Gini index.

Computational complexity analysis: Within each group, there are 300 households and 1 government. The government network consists of an actor with 20,748 parameters and a critic with 18,945 parameters, yielding a total of 39,693 parameters. The household network comprises an actor with 19,076 parameters and a critic with 19,457 parameters, totaling 38,533 parameters per household. At each training epoch, the government collects 30 trajectories and each household collects 300

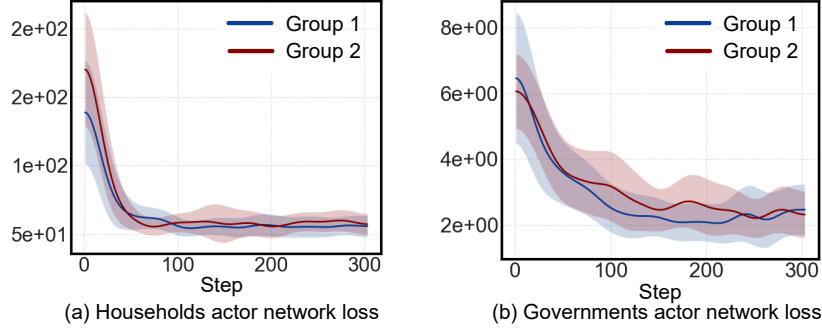

Figure 5: Actor loss convergence analysis in two group competition experiment using IPPO.

transition samples for policy updates. The government network is updated once per epoch, while the household networks are updated 300 times in aggregate, reflecting the fine-grained temporal resolution of household decision-making relative to the government’s coarser policy adjustment frequency.

Convergence analysis Formal convergence guarantees are difficult to establish in complex multi-agent game environments. Instead, we empirically demonstrate the convergence behavior of the proposed model by tracking the actor network loss of each agent during training. To mitigate the effect of randomness, we report the mean loss over ten independently sampled episodes at each training step, where the solid line represents the mean value and the shaded region indicates the corresponding variance, as shown in Figure 5.

Figure 5(a) illustrates the aggregated household actor loss within a single group. The loss converges at approximately 100 training steps (corresponding to 1,000 epochs), which validates the effectiveness of the curriculum learning schedule. Specifically, the scaling parameter ϕ , defined in Section 4.2.2, reaches its maximum value of 1 at epoch 1,000, after which the intra-group optimization is fully activated. Figure 5(b) shows the government actor loss under inter-group competition. Due to the increased complexity of multi-government strategic interactions, convergence is slower, with the loss stabilizing at approximately 250 training steps.

E Algorithm implementation

We provide the full implementation of the proposed multi-group bi-level learning framework in Algorithm 1. The training procedure operates over episodes and integrates hierarchical sampling, curriculum learning, and sequential updates.

At each time step t , households act at a fine time scale: each household j observes its state $\sigma_{\text{hh},t}^j$ together with the current government action $a_{\text{gov},t}$, and samples an action $a_{\text{hh},t}^j$. The government operates at a coarser time scale and updates its action only when $t \bmod n_{\text{gov}} = 0$, otherwise its previous action is held fixed.

Inter-group competition is controlled by the curriculum parameter ϕ , which is updated as a function of the training episode and regulates the strength of capital mobility during trajectory generation.

At the beginning of each training epoch k , a target group index i is selected. After collecting trajectories and storing them in the replay buffer $\mathcal{D}$, only the actor-critic networks associated with group i are updated, while all other groups remain fixed. This sequential update scheme provides a stationary learning target and improves training stability.

Algorithm 1 Multi-group bi-level learning framework

Require: Number of groups N , government sampling interval n_{gov} , curriculum parameter ϕ .

- 1: **Initialize:** Government parameters θ_{gov} and Household parameters θ_{hh} for all groups.
 - 2: **Initialize:** Curriculum parameter $\phi \leftarrow 0$.
 - 3: **Initialize:** Replay buffer $\mathcal{D}$.
 - 4: **for** Episode $k = 1, 2, \dots, K$ **do**
 - 5: Reset environment and obtain initial global state s_0 .
 - 6: **Select Target Group:** $i \leftarrow k \pmod{N}$
 - 7: **for** Timestep $t = 0, 1, \dots, T$ **do**
 - 8: **if** $t \pmod{n_{\text{gov}}} == 0$ **then**
 - 9: Government samples action $a_{\text{gov},t} \sim \pi_{\theta_{\text{gov}}}(s_t)$;
 - 10: **else**
 - 11: Maintain previous action $a_{\text{gov},t} \leftarrow a_{\text{gov},t-1}$;
 - 12: **end if**
 - 13: **for** each household j in all groups **do**
 - 14: Observe individual state $o_{\text{hh},t}^j$ and government action $a_{\text{gov},t}$;
 - 15: Sample action $a_{\text{hh},t}^j \sim \pi_{\theta_{\text{hh}}}(o_{\text{hh},t}^j, a_{\text{gov},t})$;
 - 16: **end for**
 - 17: Execute actions $\{a_{\text{gov},t}, \mathbf{a}_{\text{hh},t}\}$, observe rewards $r_{\text{gov},t}, \mathbf{r}_{\text{hh},t}$ and next state s_{t+1} .
 - 18: Store transition $\langle s_t, a_{\text{gov},t}, \mathbf{a}_{\text{hh},t}, r_{\text{gov},t}, \mathbf{r}_{\text{hh},t}, s_{t+1} \rangle$ in $\mathcal{D}$.
 - 19: **end for**
 - 20: Compute advantages and returns (e.g., GAE).
 - 21: Update Actor-Critic networks for **Group** i using $\mathcal{D}$.
 - 22: Clear buffer $\mathcal{D}$.
 - 23: Update curriculum parameter: $\phi \leftarrow \min(1.0, k \cdot 0.001)$.
 - 24: **end for**
-

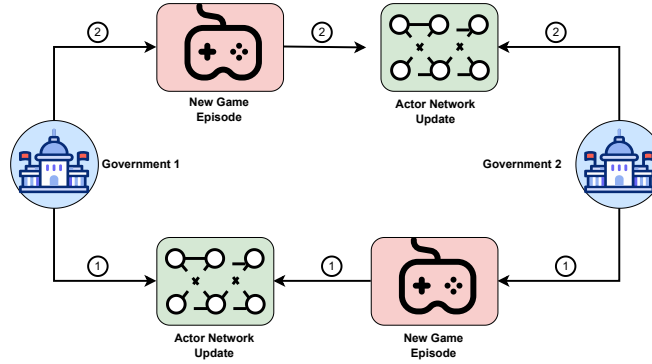

Figure 6: **Closed-Loop Sequential Update Pipeline.** There two stage in the two group competition game: In the first stage, governments 1 and 2 engage in a tax game, generating episode data used to update the policy of government 1. In the second stage, the two governments play another round of the tax game, generating new episode data to update the policy of government 2.
