Abstract

I ask whether a factor model that prices the aggregate market also prices the market’s internal components. I construct a CRSP investible market portfolio and split it into size-ranked body and tail legs that exactly recombine to the market. All models pass the aggregate market test. Yet q_5 leaves systematic, offsetting alphas: negative in the body and positive in the tail. Random splits remove the rejection. The evidence suggests that the market can appear priced because internal pricing errors cancel.

1 Introduction

Most linear factor models include the market return as a core factor. A strong fit to the market portfolio is therefore not a demanding empirical success. It is close to a built-in sanity check. I do not challenge this aggregate relation. I ask a different question. If a factor model prices the aggregate market, does it also price the market's internal components?

A value-weighted market portfolio is an average of many stocks. A small alpha for the aggregate market does not imply small alphas for the portfolios inside it. Pricing errors may have opposite signs across internal components. If so, they can cancel in the aggregate market. The aggregate zero-alpha condition is therefore necessary, but it is not a sufficient condition for internal pricing consistency.

I propose a body–tail test to study this aggregation problem. I construct an investible CRSP market portfolio from common stocks. I then split it by cumulative market capitalization into a body and a tail. At each cutoff, the body and tail are two tradable portfolios from the same universe. When I recombine them with their market weights, I recover the original market portfolio. The test therefore does not add a new anomaly portfolio. It decomposes the market portfolio itself.

I also use random splits as a matched benchmark. A random split keeps the same investible universe, formation dates, split ratios, and aggregate market portfolio. It changes only the assignment rule. Stocks are assigned to the two legs at random rather than by market-capitalization rank. If rejections appear in the body–tail split but not in the random split, they are not mechanical consequences of splitting the market. They are linked to the size-ranked structure inside the market.

I compare CAPM, the Fama–French three-factor model, the Carhart four-factor model, the Fama–French five-factor model, the six-factor model that adds momentum, and the q5 model. I first check that my production market return, cMKT, closely tracks standard market factors. I then run aggregate market sanity checks. Finally, I decompose the same market into body and tail legs. I test each leg's alpha and the joint zero-alpha restriction for the two legs.

The results show that aggregate market fit and internal market consistency are different conditions. The full production market portfolio has very high explanatory power and statistically insignificant alpha under all candidate models. Yet the body–tail decomposition reveals sharp model differences. CAPM, Carhart, FF5, and FF6 are broadly stable in the full-sample body–tail tests. q5 rejects the joint zero-alpha restriction at all nine split ratios. Under q5, the body leg repeatedly has negative alpha, while the tail leg repeatedly has positive alpha. These errors cancel when the two legs are recombined into the net market.

This q5 rejection does not appear in random splits. It also survives Newey–West lags of 5, 21, 63, and 252 trading days. Replacing the q5 market factor with cMKT does not remove the rejection. Factor-block diagnostics point away from market-factor implementation error. They instead link the body–tail tension to q5’s ROE–EG block, especially EG.

This paper makes three contributions. First, I introduce the body–tail test as an internal consistency check for factor models. The test asks whether a model that prices the market also prices the market’s own components. Second, I use random splits as a matched benchmark. This separates mechanical split effects from pricing errors tied to the size-ranked structure of the market. Third, I use cMKT substitutions and factor-block diagnostics to show that the rejection is not a market-factor artifact. It is connected to specific nonmarket factor blocks.

The results do not imply that one factor model is inferior under every criterion. A model may expand the mean–variance frontier and pass spanning tests, yet still leave pricing errors on externally given test assets. I show that the same point applies inside the market portfolio. The market can appear priced because opposite internal errors cancel. Aggregate market fit is therefore not enough. Internal pricing consistency is a separate object of factor-model evaluation.

2 Theoretical Background and Related Literature

2.1 Linear Factor Models and Pricing Errors

Linear factor models summarize common variation in asset returns with a small set of factors. They explain expected returns through exposures to these factors. Let $R_{i,t}^e$ denote the excess return on test asset i , and let f_t denote a K -vector of factor returns. The standard time-series test estimates

$$R_{i,t}^e = \alpha_i + \beta_i' f_t + \varepsilon_{i,t}, \quad i = 1, \dots, N. \quad (1)$$

The intercept α_i is the pricing error. If $\alpha_i = 0$ for all test assets, the factor model prices the given test assets without time-series pricing errors. The GRS test of [Gibbons et al. \(1989\)](#) is the standard joint test of this restriction.

The same logic follows from the stochastic discount factor (SDF) approach. A valid SDF must satisfy the pricing conditions for all traded assets. A factor model can be viewed as a low-dimensional approximation to such an SDF ([Cochrane, 2005](#)). [Hansen and Jagannathan \(1997\)](#) provide a general distance-based framework for measuring SDF misspecification. [Kozak et al. \(2018\)](#) show that, even when many return patterns exist, an economically meaningful SDF may be approximated by a small number of dominant components. Thus,

factor-model evaluation is not only about which anomalies a model explains. It is also about which pricing errors the SDF approximation leaves on a given set of assets.

Alpha tests alone, however, do not fully rank tradable factor models. [Barillas and Shanken \(2017\)](#) show that model comparison should focus on whether one model spans the factors of another model. This criterion is directly linked to maximum Sharpe ratios. [Barillas and Shanken \(2018\)](#) also compare models through the mean–variance investment opportunity set generated by tradable factors. I take this point seriously. The body–tail test does not replace maximum-Sharpe-ratio or spanning criteria. It provides a complementary test. It asks how pricing errors are structured inside a given market portfolio.

2.2 Aggregate Market Alpha and Internal Consistency

Most linear factor models include the market return as a core factor. In the CAPM, the market return is the only systematic risk factor. In the Fama–French and q-factor families, the market factor is also a basic component. A high R^2 for the aggregate market portfolio is therefore not a demanding success when the model already contains a market factor. If the market portfolio is measured from data close to the factor itself, a small aggregate market alpha is closer to a weak sanity check than to strong evidence of pricing ability.

A small alpha for the aggregate market does not imply small alphas for the portfolios inside the market. In a simple fixed-weight case, suppose the market portfolio M is a combination of two tradable portfolios, B and T :

$$R_{M,t}^e = w_B R_{B,t}^e + w_T R_{T,t}^e, \quad w_B + w_T = 1. \quad (2)$$

Under the same factor model, the market alpha is the weighted average of the two internal alphas:

$$\alpha_M = w_B \alpha_B + w_T \alpha_T. \quad (3)$$

Thus, $\alpha_M = 0$ does not imply $\alpha_B = \alpha_T = 0$. Internal pricing errors can have opposite signs and cancel in the aggregate. In the empirical buy-and-hold setting, the market weights of the legs vary over time. This does not change the main point. Aggregate zero alpha is weaker than zero alpha for the internal legs.

The body–tail test evaluates this aggregation problem. I split the market into a body and a tail by cumulative market capitalization. The dynamic value-weighted combination of the two legs reconstructs the same market portfolio. The test therefore does not add an external anomaly portfolio. It uses the market portfolio’s own internal components as test assets. If the aggregate market passes but the body and tail jointly have nonzero alphas, the

model prices the market return but fails to price the market’s internal relative returns.

2.3 Test-Asset Construction and Model Evaluation

Empirical factor-model performance can depend on how test assets are constructed. Traditional cross-sectional asset-pricing tests often use portfolios sorted on firm characteristics such as size, value, profitability, investment, and momentum. The Fama–French three-factor model reflects the size and value patterns (Fama and French, 1992, 1993). The five-factor model adds profitability and investment factors (Fama and French, 2015). Momentum became a central return pattern after Jegadeesh and Titman (1993), and Carhart (1997) introduced it into a four-factor performance-evaluation model.

When test assets and candidate factors share similar sorting rules, good fit can reflect both general pricing ability and alignment with the test-asset design. Lo and MacKinlay (1990) discuss data-snooping concerns in asset-pricing tests. Lewellen et al. (2010) show that tests can be sensitive to the structure of test portfolios. Giglio et al. (2025) also emphasize the importance of test assets and weak factors in factor-model evaluation. Shin (2026) studies this construction dependence using CRSP-based random portfolios that are not presorted on firm characteristics. The paper shows that stock selection, initial weights, holding rules, and dynamic weight management can change model rankings.

I bring this issue inside the market portfolio. Body–tail portfolios are not standard anomaly portfolios. They are internal components of the same market portfolio, formed by cumulative market-capitalization rank. I also use random splits as matched null benchmarks. A random split keeps the same universe and the same split ratio, but assigns stocks to the two legs at random rather than by market-capitalization rank. If pricing errors concentrate in body–tail splits but not in random splits, the result is not a mechanical effect of splitting the market. It is tied to the size-ranked structure inside the market.

2.4 Benchmark Factor Models and the Position of This Paper

I compare standard factor models that are widely used for U.S. equity returns. The Fama–French three-factor model includes the market, size, and value factors (Fama and French, 1993). The five-factor model adds profitability and investment factors (Fama and French, 2015). Fama and French (2018) discuss factor selection and the economic interpretation of model construction. The Carhart four-factor model combines the Fama–French three-factor model with momentum (Carhart, 1997).

The q-factor family is based on investment-based asset-pricing theory. Hou et al. (2015) propose a q-factor model with market, size, investment, and profitability factors. Hou et al.

(2019) compare the importance of competing factors. Hou et al. (2021) add an expected-growth factor and propose q5. Hou et al. (2020) discuss anomaly replication and the importance of data treatment. Hou et al. (2024) analyze the implications of security-analysis information for return prediction and factor construction.

These models all include a market factor. But they do not directly test whether they price the market’s internal components at the same time. This paper differs from the literature in three ways. First, I use an internal decomposition of the market portfolio as test assets, rather than traditional characteristic-sorted or external anomaly portfolios. Second, I compare body–tail results with random splits. This separates mechanical split effects from pricing errors linked to the size-ranked structure of the market. Third, I use cMKT substitutions and factor-block diagnostics to distinguish market-factor implementation error from pricing errors associated with specific nonmarket factor blocks.

The goal is not to choose a single model that is best under every criterion. I identify internal pricing errors that can be hidden at the aggregate market level. Factor-model evaluation should therefore consider not only aggregate market fit, but also the pricing consistency of the market’s own components.

3 Data and Methodology

3.1 CRSP Universe Selection

I use daily CRSP stock data to construct an investible universe for the U.S. equity market. The sample runs from January 3, 1967 to December 31, 2024. The base sample consists of common stocks listed on the NYSE, AMEX, and NASDAQ. The screening rule has a simple goal. It keeps almost all of the market’s economic scale and trading activity, while removing the extreme microcap and illiquidity tails.

I update investibility at each month-end. I use both market capitalization and trading liquidity. For stock i , month-end market capitalization is

$$ME_{i,t} = |PRC_{i,t}| \times SHROUT_{i,t} \times 1,000. \quad (4)$$

I sort stocks in descending order of market capitalization at each month-end. I then compute each stock’s cumulative market-capitalization share as

$$CumME_{i,t} = \frac{\sum_{j:ME_{j,t} \geq ME_{i,t}} ME_{j,t}}{\sum_j ME_{j,t}}. \quad (5)$$

I measure trading liquidity by average dollar volume over the most recent 63 trading days ending at the month-end:

$$DVOL_{i,d} = |PRC_{i,d}| \times VOL_{i,d}, \quad (6)$$

$$ADV63_{i,t} = \frac{1}{N_{i,t}} \sum_{d \in \mathcal{W}_t} DVOL_{i,d}. \quad (7)$$

Here $\mathcal{W}_t$ is the set of the most recent 63 trading days ending at month-end t . $N_{i,t}$ is the number of days in that window with observed dollar volume. I use monthly cross-sectional percentiles of $ADV63$, rather than an absolute dollar-volume cutoff. This avoids a fixed nominal threshold over a long sample with large changes in prices and market size.

The selection rule uses hysteresis. An incumbent stock exits the universe if $CumME_{i,t} > 0.999$ or if its $ADV63$ falls to the bottom 2.5% of the monthly cross-section. A stock outside the universe enters only if $CumME_{i,t} \leq 0.995$ and its $ADV63$ reaches at least the fifth percentile. The entry rule is stricter than the stay rule. This reduces repeated entry and exit near the boundary.

Historical NASDAQ volume data are limited in some early periods. I therefore give NASDAQ stocks a short liquidity grace period. After volume first appears, I defer the liquidity screen until 63 trading days of volume history are available. The market-capitalization screen still applies. All screening variables use only information observed by the relevant month-end. The universe determined at a month-end applies from the first trading day of the next month. This timing prevents look-ahead bias.

Across the full sample, the final universe includes an average of 77.6% of the common-stock base sample. It preserves about 99.7% of total market capitalization and 63-day average dollar volume. At the end of December 2024, it includes 2,426 of 3,804 base-sample stocks. The market-capitalization and dollar-volume preservation rates are 99.78% and 99.28%, respectively. The screen therefore removes the extreme illiquidity tail while keeping almost all of the market’s economic weight.

3.2 Market-Factor Replication

The body–tail test starts from an investible market portfolio that I construct directly from CRSP individual stocks. I therefore first check whether later alpha tests could be driven by market-return implementation error. I construct a value-weighted market return from the investible CRSP universe defined above. I denote this return by $cMKT$. It is the benchmark market return that the body–tail and random-split portfolios must reconstruct. It is also the series that I use to evaluate implementation differences relative to standard market factors.

Replicating a market factor is not just a matter of value-weighting all stocks. Small differences can arise from delisting returns, dividend-inclusive returns, formation dates, market-capitalization coverage, and the treatment of very small or illiquid stocks. These differences are tiny at the daily frequency. Yet they can accumulate over long samples and appear as statistically significant intercepts in factor-model regressions. To reduce these implementation gaps, I combine market capitalization, dividend-inclusive returns, delisting returns, and trading-liquidity information from the CRSP source files.

I compute $cMKT$ as a daily value-weighted buy-and-hold portfolio. The investible universe is fixed at each month-end and applied from the first trading day of the next month. Initial weights use market capitalization at the formation date. Returns are dividend-inclusive. When delisting returns are observed, I incorporate them. Dividends and delisting cash flows inside the portfolio are reinvested proportionally into surviving stocks. This procedure does not aim to reverse-engineer any provider’s exact market factor. It asks whether an independently constructed investible CRSP market return is close enough to the Fama–French and q5 market factors for the later tests to be meaningful.

Replication performance is very high. In the common sample from January 3, 1967 to December 31, 2024, the correlation between $cMKT$ and the Fama–French market return is 0.999778. The regression R^2 is 0.999556. The daily RMSE is 2.21 bp, and the mean absolute error is 1.35 bp. The comparison with the q5 market return is similarly close. The correlation is 0.999799, and the regression R^2 is 0.999598. The daily RMSE and mean absolute error are 2.10 bp and 1.27 bp. In both comparisons, the regression beta is very close to one. The intercept is economically small. Figure 3.1 shows the same relation in scatter plots. Most observations lie close to the 45-degree line. This confirms that $cMKT$ closely tracks the daily variation in both standard market factors.

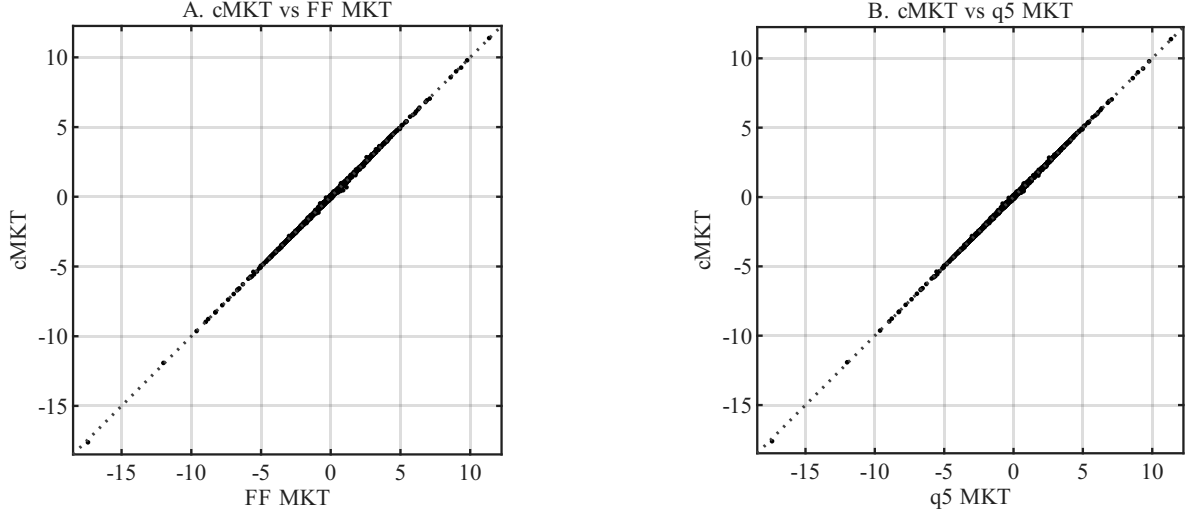

Figure 3.1: CRSP-based market return and standard market factors

Note: The figure reports daily scatter plots of $cMKT$, the market return that I construct from the CRSP investible universe, against the Fama–French and q5 market returns. The comparison uses total market returns after adding each provider’s risk-free rate back to the excess market return. The dashed line is the 45-degree line. The common sample runs from January 3, 1967 to December 31, 2024.

High replication accuracy does not mean that market-return construction is automatically robust. In constructing $cMKT$, long-run alpha tests are sensitive to delisting-return treatment, dividend cash-flow reinvestment, universe formation dates, market-capitalization coverage, and the inclusion of illiquid stocks. Even small daily implementation differences can affect intercept significance over several decades. I therefore use the $cMKT$ comparison as more than a data check. It is a diagnostic step. It helps separate pricing errors caused by small market-factor implementation gaps from pricing errors inside the market portfolio.

The final $cMKT$ also passes a basic market-return sanity check. Since each candidate model contains a market factor, the intercept should be close to zero when the full market portfolio is the test asset. Table 3.1 reports regressions of the full investible market return on each candidate model. All models have R^2 above 0.999. Using a 21-day Newey–West lag, all alpha p -values exceed 0.05. The later body–tail pricing errors are therefore unlikely to arise because the aggregate market return itself is not priced by the candidate models.

Unless stated otherwise, I report all main tests with a Newey–West lag of 21 trading days. I also check lags of 5, 63, and 252 trading days. The main conclusions do not change. In particular, the q5 body–tail joint-alpha rejection holds for all nine split ratios under all HAC lags.

Table 3.1: Market sanity check for the full market return

Model	Observations	Annual alpha (bp)	$t(\alpha)$	$p(\alpha)$	R^2
CAPM	14,598	-1.02	-0.22	0.829	0.999556
FF3	14,598	0.21	0.05	0.963	0.999571
Carhart	14,598	-0.06	-0.01	0.989	0.999571
FF5	14,598	-1.07	-0.24	0.812	0.999572
FF6	14,598	-1.18	-0.26	0.792	0.999572
q5	14,598	-5.78	-1.44	0.151	0.999619

Note: The table reports regressions of the full investible market return constructed in this paper on each candidate factor model. Alpha is the daily intercept multiplied by 252 and reported in basis points per year. All tests use the common sample from January 3, 1967 to December 31, 2024. The p -values use a Newey–West lag of 21 trading days.

The pass in Table 3.1 should be interpreted as a consistency gate. It does not imply that market-return implementation issues disappear. With longer HAC lags, the q5 alpha for the aggregate market remains insignificant at the 5% level, but its p -value moves closer to the boundary. This shows that precise market-factor construction is a sensitive task in long daily samples. Still, in the baseline test, all candidate models price the same full market portfolio. Later leg-level pricing errors are therefore best interpreted as failures of internal decomposition consistency, not as failures of the aggregate market test itself.

The replication exercise also does not claim that $cMKT$ exactly replicates the Fama–French or q5 market factor. The exact universe, filters, return treatment, and reinvestment rules may differ across data providers. The point is narrower. An independently constructed market return from CRSP source data produces a series that is empirically almost identical to standard market factors. The later body–tail pricing errors are therefore hard to explain as simple market-factor implementation errors.

I also run robustness tests that replace the original Fama–French or q5 market factor with $cMKT$. These tests control implementation differences more directly. They ask whether the results depend on a particular provider’s market definition or on small gaps that accumulate over the long sample. They also ask whether the results survive when I use the same CRSP-based market return that generates the body–tail portfolios.

3.3 Body–Tail Test

The core test decomposes the full market portfolio into a body and a tail. It then asks whether the same factor model prices both internal components at the same time. At each portfolio formation date τ , I sort all investible stocks by market capitalization in descending

order. I define the body as the stocks whose cumulative market-capitalization share is at or below the split ratio p . I define the tail as the remaining stocks. I use

$$p \in \{0.50, 0.60, 0.75, 0.80, 0.85, 0.90, 0.95, 0.975, 0.99\}.$$

This grid covers a wide range of market decompositions. It includes both balanced body–tail splits and cases that isolate a very small tail.

In the baseline analysis, I form portfolios at the end of June each year. I use the investible universe and market-capitalization ranks observed at that date. The split applies from the first trading day of the following July through the end of the next June. This annual formation structure is close to the standard Fama–French timing convention. It also prevents high-frequency noise in daily returns from driving the split boundary. I compute leg returns as value-weighted buy-and-hold returns with initial weights based on market capitalization at formation. Dividend-inclusive returns and delisting returns are treated in the same way as in the construction of the full market return. Cash flows generated inside a leg are reinvested proportionally into surviving stocks.

Let $w_{p,\tau}^B$ and $w_{p,\tau}^T$ be the initial market-value shares of the body and tail at formation date τ for split ratio p . Then

$$w_{p,\tau}^B + w_{p,\tau}^T = 1.$$

During the buy-and-hold period, however, the market shares of the two legs vary with realized returns and reinvested cash flows. The daily reconstruction identity therefore uses previous-day-end leg market-value shares:

$$R_{M,d}^e = w_{p,d-1}^B R_{B,p,d}^e + w_{p,d-1}^T R_{T,p,d}^e, \quad w_{p,d-1}^B + w_{p,d-1}^T = 1.$$

Here $R_{M,d}^e$ is the excess return on the full investible market portfolio. $R_{B,p,d}^e$ and $R_{T,p,d}^e$ are the excess returns on the body and tail portfolios. $w_{p,d-1}^B$ and $w_{p,d-1}^T$ are the body and tail market-value shares immediately before trading day d . The body and tail are therefore not external test assets added to the market. They are internal legs of the same market portfolio.

I estimate pricing errors for each leg with standard time-series regressions:

$$R_{\ell,p,d}^e = \alpha_{\ell,p} + \beta'_{\ell,p} f_d + \varepsilon_{\ell,p,d}, \quad \ell \in \{B, T\}.$$

Here f_d is the daily factor return vector for a candidate model. I test each leg alpha separately. I also test the joint zero-alpha restriction

$$H_0 : \alpha_{B,p} = \alpha_{T,p} = 0.$$

The joint test is a Wald test that uses the residual covariance between the two legs. I use Newey–West covariance matrices to allow for heteroskedasticity and serial correlation in daily returns. The baseline lag is 21 trading days.

The key object is the difference between aggregate market alpha and internal leg alpha. In a fixed-weight example, the market alpha can be read as the value-weighted average of the internal leg alphas. In my empirical buy-and-hold portfolios, the exact daily reconstruction uses time-varying previous-day leg weights. I therefore also estimate the alpha of the recombined net portfolio and verify the reconstruction identity numerically. The main point is unchanged. A small and statistically insignificant market alpha does not imply that $\alpha_{B,p}$ and $\alpha_{T,p}$ are both zero. If the two internal leg alphas have opposite signs, they can cancel in the aggregate market return. The body–tail test examines this cancellation. It asks whether a candidate model prices not only the full market return, but also the internal market-capitalization blocks that compose it.

3.4 Random Split Test

I use random splits to distinguish size-ranked pricing errors from mechanical split effects. The random-split test uses the same investible universe, formation dates, holding periods, and split ratios as the body–tail test. The only change is the assignment rule. Instead of assigning stocks by market-capitalization rank, I assign them to two groups at random at each formation date.

Each random split is matched to a body–tail split ratio. For example, if the body–tail test uses $p = 0.80$, the random split also forms one leg that contains approximately 80% of total market value and another leg that contains the remaining 20%. This makes the two tests share the same aggregate market portfolio and similar leg-level market-value shares. The difference is whether assignment follows the size rank or a random order.

Specifically, at formation date τ , I randomly permute the investible stocks. I assign stocks to the random A-leg until cumulative market capitalization reaches p . The remaining stocks form the random B-leg. As in the body–tail test, each random pair satisfies the market reconstruction identity using previous-day-end leg market-value shares:

$$R_{M,d}^e = w_{p,d-1}^A R_{A,p,d}^e + w_{p,d-1}^B R_{B,p,d}^e, \quad w_{p,d-1}^A + w_{p,d-1}^B = 1.$$

Here $R_{A,p,d}^e$ and $R_{B,p,d}^e$ are the excess returns on the two random-split legs. I test individual leg alphas and joint alphas with the same factor models, sample period, and baseline Newey–West lag as in the body–tail test.

The random split is not a structural simulation under the null that a factor model is

true. It is an empirical matched-null benchmark. It shows what kinds of pricing errors can arise simply from dividing the market into two value-weighted tradable portfolios. This matters because the tail leg becomes smaller as the split ratio rises. Smaller legs can have higher volatility and less precise alpha estimates. Comparing each body–tail result with a random split at the same split ratio controls for these mechanical size effects and estimation uncertainty.

The interpretation is direct. If leg-level alphas and joint-alpha rejections appear with similar magnitude and frequency in both body–tail and random splits, the result is likely to be a product of the split procedure. If random-split errors are small or directionless while the body–tail split shows a systematic alpha pattern, then the pricing error is not a mechanical split effect. It is linked to the size-ranked structure inside the market.

I therefore treat the random split as a matched null benchmark, not as a secondary robustness check. The body–tail split preserves the market’s size-ranked structure. The random split keeps the same market portfolio and split ratio but removes that structure. The difference between the two results is the main evidence on whether factor-model pricing errors concentrate along the market’s systematic size hierarchy.

4 Spanning Tests Across Factor Models

Before turning to the body–tail test, I examine mean–variance inclusion relations among traded factor models. The main question in this paper is whether each model prices the internal components of the market when I decompose the aggregate market portfolio. This internal consistency test has a different objective from model comparison based on maximum Sharpe ratios. As [Barillas and Shanken \(2017\)](#) show, when traded factor models are compared by their maximum Sharpe ratios, the key issue is not the alpha of a common set of test assets. It is whether one model spans the traded factors of another model. The spanning tests in this section therefore provide a baseline for the investment opportunity sets of the candidate models. They do not replace the body–tail pricing-error analysis that follows ([Hou et al., 2019](#)).

This baseline is important for interpretation. If a model leaves significant pricing errors in the body–tail test, this does not by itself imply that the model is inferior in the mean–variance sense. Conversely, a model that offers a larger investment opportunity set in a spanning test may still fail to price the internal components of the market portfolio. This section separates these two evaluation criteria.

4.1 Test Design

FF6 consists of the market, size, value, profitability, investment, and momentum factors. q5 consists of the market, size, investment, return-on-equity, and expected-growth factors. In portfolio pricing tests, I use each provider’s market factor and risk-free rate. In the mutual spanning tests, however, I use a common market factor. This avoids putting two almost identical market factors on the two sides of the same regression. The baseline results use the Fama–French market factor. I also check the results with the global-q market factor.

I define the nonmarket factor blocks as

$$\begin{aligned} g_t^q &= (ME_t, IA_t, ROE_t, EG_t)', \\ g_t^{FF} &= (SMB_t, HML_t, RMW_t, CMA_t, MOM_t)'. \end{aligned}$$

I then estimate the following mutual spanning regressions:

$$g_t^q = \alpha_{q|FF6} + B_{q|FF6} f_t^{FF6} + \mathbf{u}_{q,t}, \quad (8)$$

$$g_t^{FF} = \alpha_{FF|q5} + B_{FF|q5} f_t^{q5} + \mathbf{u}_{FF,t}. \quad (9)$$

The null hypotheses are $H_0 : \alpha_{q|FF6} = \mathbf{0}$ and $H_0 : \alpha_{FF|q5} = \mathbf{0}$. I test the joint intercepts with the GRS test and with a HAC Wald test based on Newey–West covariance matrices. The HAC lag is 21 trading days for daily data and 6 months for monthly data.

The common daily sample runs from January 3, 1967 to December 31, 2024 and contains 14,598 observations. The monthly sample, obtained by compounding daily returns within calendar months, contains 696 observations. I measure the economic contribution of the excluded factor block by

$$\Delta \text{SR}^2 = \hat{\alpha}' \hat{\Sigma}_u^{-1} \hat{\alpha}. \quad (10)$$

The maximum Sharpe ratio summarizes the size of the in-sample investment opportunity set. The spanning decision is based on the joint intercept tests.

4.2 Joint and Factor-Level Spanning Results

Table 4.1 reports the joint spanning results with the Fama–French market factor used as the common market factor. In daily data, both spanning null hypotheses are strongly rejected. Neither model fully absorbs the other model’s nonmarket factors. The economic magnitudes, however, are asymmetric. Adding the q5-specific factors to FF6 raises the annualized maximum Sharpe ratio from 1.311 to 2.205. The annualized ΔSR^2 is 3.143. Adding the FF6-specific factors to q5 raises the maximum Sharpe ratio from 2.077 to 2.205. The

annualized ΔSR^2 is 0.549.

Table 4.1: Joint Spanning Tests Across Factor Models and Maximum Sharpe Ratios

Frequency	Null hypothesis	GRS	GRS p	HAC Wald	HAC p	SR_0	ΔSR^2
Daily	$\text{FF6} \supseteq \text{q5}$	45.197	< 0.001	148.177	< 0.001	1.311	3.143
Daily	$\text{q5} \supseteq \text{FF6}$	6.248	< 0.001	23.086	< 0.001	2.077	0.549
Monthly	$\text{FF6} \supseteq \text{q5}$	34.500	< 0.001	114.540	< 0.001	1.222	2.687
Monthly	$\text{q5} \supseteq \text{FF6}$	2.217	0.051	11.426	0.044	1.982	0.255

Notes: $\text{FF6} \supseteq \text{q5}$ is the null that FF6 jointly spans the q5-specific factors ME, IA, ROE, and EG. $\text{q5} \supseteq \text{FF6}$ is the null that q5 jointly spans the FF6-specific factors SMB, HML, RMW, CMA, and MOM. SR_0 is the annualized sample maximum Sharpe ratio of the benchmark model. ΔSR^2 is the annualized increase in the squared maximum Sharpe ratio from adding the other model’s factor block. The reported results use the Fama–French market factor as the common market factor. The spanning decisions are unchanged when I use the global-q market factor. The HAC lag is 21 for daily data and 6 for monthly data.

The monthly results lead to the same conclusion in one direction. The null that FF6 spans q5 is strongly rejected. In the opposite direction, the GRS p -value is 0.051 and the HAC p -value is 0.044. The 5% decision therefore depends on the inference method. The results are almost unchanged when I use the global-q market factor. The monthly data suggest that q5 absorbs much of the FF6-specific factor block, but they do not support a robust conclusion of complete spanning.

These results provide a useful baseline for the body–tail tests. From the spanning and maximum-Sharpe-ratio perspective, q5 has strong evidence in its favor relative to FF6. Therefore, if q5 later leaves significant pricing errors in some body–tail splits or regimes, the result cannot be reduced to the claim that q5 is a generally weak factor model. The contrast is sharper. The same model can look strong by mean–variance spanning and still look fragile by the aggregation-consistency criterion inside the market portfolio.

Table 4.2 shows the factor-level source of this asymmetry. FF6 almost completely absorbs q5 ME, and it makes IA insignificant at the 5% level. In contrast, ROE and EG leave significant annualized alphas of 313.6 bp and 864.4 bp. EG is especially important. Its individual ΔSR^2 is 2.425, which makes it the main source of the q5 block’s expansion of the FF6 investment opportunity set.

In the opposite direction, q5 absorbs HML, RMW, CMA, and MOM to a large extent. SMB remains significant, with an annualized alpha of 92.3 bp. The borderline monthly joint test mainly reflects this size factor. The joint spanning statistic also uses the residual covariance matrix. Thus individual ΔSR^2 values should not be added mechanically.

Table 4.2: Monthly Factor-Level Spanning Regressions

Benchmark model	Target factor	Annualized alpha (bp)	HAC p	R^2	Individual ΔSR^2
<i>Panel A: Pricing q5-specific factors with FF6</i>					
FF6	ME	17.6	0.605	0.950	0.005
FF6	IA	74.6	0.070	0.855	0.074
FF6	ROE	313.6	< 0.001	0.642	0.347
FF6	EG	864.4	< 0.001	0.449	2.425
<i>Panel B: Pricing FF6-specific factors with q5</i>					
q5	SMB	92.3	0.006	0.956	0.170
q5	HML	119.8	0.348	0.485	0.025
q5	RMW	13.3	0.895	0.473	0.001
q5	CMA	-13.7	0.755	0.861	0.003
q5	MOM	-42.0	0.843	0.277	0.001

Notes: The sample covers 696 months from January 1967 to December 2024. Alphas are monthly intercepts multiplied by 12 and reported in basis points. HAC p -values use a Newey–West lag of 6 months. Individual ΔSR^2 is the annualized increase in the squared maximum Sharpe ratio from adding each target factor alone to the benchmark model.

In sum, the spanning tests provide a relatively favorable baseline for q5. ROE and EG expand the investment opportunity set beyond FF6 by economically large amounts. In monthly data, q5 also absorbs much of the FF6 factor block. The body–tail evidence below should therefore not be read as evidence that q5 is inferior in the overall mean–variance sense. I make a narrower point. A model can be strong under mean–variance spanning and still fail to price the internal components of the market when the market is decomposed by its size-ranked structure.

5 Full–Period Empirical Results

As the market-level sanity check shows, my production market portfolio is almost perfectly explained by the standard factor models. The tests below therefore do not start from a market return that the models already fail to price. They ask a more specific question. Do pricing errors that are hidden in the aggregate market appear when I decompose the market along its size-ranked structure?

5.1 Body–Tail Test

Table 5.1 summarizes the full-period body–tail tests. For each split ratio p , the body leg contains the stocks in the top p share of cumulative market capitalization at the formation date. The tail leg contains the remaining stocks. I use

$$p \in \{0.50, 0.60, 0.75, 0.80, 0.85, 0.90, 0.95, 0.975, 0.99\}.$$

For each pair, I test the null that the two leg alphas are jointly zero using a Wald test.

The results differ sharply across models. CAPM, Carhart, FF5, and FF6 do not reject the joint zero-alpha null at any split ratio under the baseline HAC lag. FF3 rejects at some split ratios, but it does not reject the net-alpha test. q5 is different. It rejects the joint zero-alpha null at all nine split ratios. Its average body alpha is negative. Its average tail alpha is positive. Thus, pricing errors that are hidden in the aggregate market appear as opposite-signed leg-level alphas once I decompose the market by size rank.

Table 5.1: Full-period body–tail tests

Model	Joint reject (/9)	Alpha-sum reject (/9)	Net reject (/9)	Body α (bp/yr)	Tail α (bp/yr)	Median joint p
CAPM	0/9	0/9	0/9	-18.3	82.3	0.775
FF3	4/9	4/9	0/9	18.5	-101.6	0.212
Carhart	0/9	0/9	0/9	7.0	-32.0	0.612
FF5	0/9	0/9	0/9	-3.1	-13.6	0.721
FF6	0/9	0/9	0/9	-10.7	36.2	0.588
q5	9/9	8/9	0/9	-56.2	181.0	6.25×10^{-5}

Notes: The table summarizes body–tail pair tests across nine split ratios, $p \in \{0.50, 0.60, 0.75, 0.80, 0.85, 0.90, 0.95, 0.975, 0.99\}$. The sample is the common daily sample, 1967–2024, with Newey–West 21 daily lags. “Joint reject” counts rejections of the two-leg zero-alpha Wald test at the 5% level. “Alpha-sum reject” counts rejections for the unweighted sum of the two leg alphas. “Net reject” counts rejections for the value-weighted net market portfolio reconstructed from the two legs.

Table 5.2 reports the q5 results by split ratio. Under q5, the body alpha is negative at every split ratio. The tail alpha is positive at every split ratio. The tail alpha also remains positive when the tail becomes small. This sign pattern suggests that the q5 rejection is not a chance outcome at one cutoff. It is a repeated internal pricing error along the size-ranked structure of the market.

Table 5.2: q5 body–tail alphas by split ratio

Split p	Body α (bp/yr)	Tail α (bp/yr)	t_A	t_B	Joint p	$\alpha_A + \alpha_B$ (bp/yr)	Sum p
0.500	-158.4	147.9	-4.54	4.37	3.30×10^{-5}	-10.5	0.191
0.600	-119.4	165.4	-4.60	4.47	2.57×10^{-5}	45.9	7.40×10^{-4}
0.750	-74.6	201.1	-5.01	5.00	2.40×10^{-6}	126.5	2.47×10^{-6}
0.800	-59.1	207.8	-5.03	5.14	1.21×10^{-6}	148.7	8.36×10^{-7}
0.850	-38.0	177.1	-4.17	4.29	6.25×10^{-5}	139.1	3.82×10^{-5}
0.900	-23.8	156.5	-3.37	3.53	0.001	132.7	6.75×10^{-4}
0.950	-14.4	159.1	-2.71	2.94	0.007	144.6	0.005
0.975	-9.8	152.0	-2.11	2.23	0.040	142.2	0.031
0.990	-8.5	262.0	-1.98	2.90	0.009	253.5	0.004

Notes: This table reports the q5 body–tail results for each split ratio in the common daily sample with Newey–West 21 daily lags. A denotes the body leg and B denotes the tail leg. Alphas are annualized basis points. The net reconstructed market alpha is -5.8 bp per year with $p = 0.151$ for every split ratio because the two legs exactly reconstruct the same production market return.

The key point is that these leg-level pricing errors do not become aggregate market pricing errors. When I recombine the two legs with value weights, I recover the original production market portfolio. The net alpha is insignificant for all models. The q5 body–tail rejection is therefore not a failure to price the market as a whole. It is a failure to price the market’s internal components jointly.

5.2 Random Split as a Matched Null Benchmark

I use random splits to separate size-ranked pricing errors from mechanical split effects. For each split ratio p , the body–tail test assigns stocks by cumulative market capitalization. The random split keeps the same investible universe and the same split ratio. It assigns stocks to the two legs at random rather than by size rank.

In this design, both the body–tail pair and the random-split pair are normalized so that the value-weighted average of the two legs reconstructs the same aggregate market portfolio. The two tests therefore share the same aggregate market return, leg market weights, sample period, regression model, and test statistic. Only the assignment rule changes. The body–tail test keeps the size-ranked structure. The random split removes it.

The random split is not a structural null in which the factor model is assumed to be true. It is an empirical benchmark for the pricing errors that can arise when the market is

split into two tradable portfolios. This matters because the tail leg becomes small as the split ratio rises. Its return volatility and alpha estimation error may rise mechanically. By comparing each body–tail result with random splits at the same split ratio, I control for these mechanical size and estimation effects.

The interpretation is direct. If leg-level alphas and joint-alpha rejections appear with similar size and frequency in the body–tail and random splits, then the result is likely to come from the split procedure itself. If random splits show weak and directionless pricing errors while the body–tail split shows systematic rejections, then the pricing errors are linked to the size-ranked structure inside the market.

Table 5.3 compares the body–tail results with the random-split benchmark. For q5, the random-split joint rejection rate is 4.1%, which is close to the nominal level. This shows that q5 does not mechanically fail for every split of the market. Even when I split the same market portfolio into two legs at the same ratios, q5 pricing errors weaken sharply once I remove the size-ranked assignment rule. By contrast, q5 rejects at all split ratios in the body–tail test. This contrast shows that the full-period q5 rejection is not a simple split effect. It is revealed by the size-ordered decomposition.

Table 5.3: Body–tail tests versus random-split matched nulls

Model	BT joint reject (/9)	Random joint reject (%)	BT sum reject (/9)	Random sum reject (%)	BT net reject (/9)	Random net reject (%)
CAPM	0/9	2.3	0/9	5.3	0/9	0.0
FF3	4/9	13.2	4/9	18.0	0/9	0.0
Carhart	0/9	8.6	0/9	13.2	0/9	0.0
FF5	0/9	15.6	0/9	20.0	0/9	0.0
FF6	0/9	12.6	0/9	17.3	0/9	0.0
q5	9/9	4.1	8/9	5.1	0/9	0.0

Notes: “BT” denotes the deterministic body–tail split. Random-split rejection rates are weighted averages across the same nine split ratios, with 500 random pairs per ratio and model. All tests use the common daily sample and Newey–West 21 daily lags. The random split preserves the same investible universe, split ratio, net market portfolio, factor model, sample period and test statistic; only the size-ranked assignment rule is removed.

Table 5.4 gives the same comparison by split ratio for q5. The body–tail joint test rejects at the 5% level for every split ratio. The matched random-split joint rejection rate remains low for most split ratios. Even at $p = 0.99$, where the tail is very small, the random-split joint rejection rate is only 8.2%. Thus, the q5 body–tail rejection is not mechanically produced by a small tail leg. It is concentrated in the tail leg defined by market-capitalization rank.

Table 5.4: Matched random-split benchmark for q5

Split p	BT joint p	Random joint reject (%)	Random sum reject (%)	Random $ \alpha_A $ (bp/yr)	Random $ \alpha_B $ (bp/yr)
0.500	3.30×10^{-5}	3.0	0.0	18.9	19.1
0.600	2.57×10^{-5}	1.4	2.0	15.4	22.3
0.750	2.40×10^{-6}	2.8	3.8	10.7	30.2
0.800	1.21×10^{-6}	3.4	4.6	9.9	36.8
0.850	6.25×10^{-5}	2.8	5.0	8.9	43.3
0.900	0.001	3.8	5.8	7.6	52.9
0.950	0.007	5.4	8.0	6.6	77.0
0.975	0.040	6.0	7.8	6.1	104.9
0.990	0.009	8.2	8.6	5.8	152.5

Notes: For each split ratio, the table compares the deterministic q5 body–tail joint-test p -value with the empirical rejection rate from 500 matched random splits. All tests use Newey–West 21 daily lags. Random-split alpha magnitudes are mean absolute annualized alphas across the 500 random pairs.

6 Subperiod Empirical Results

I next ask whether the full-sample results are driven by one isolated period. I repeat the body–tail tests in calendar subperiods, rolling 10-year windows, and q5-detected regimes. Unless stated otherwise, all tests use the common daily sample and Newey–West standard errors with 21 trading-day lags.

6.1 Calendar subperiods

I first split the common sample into calendar subperiods. Table 6.1 reports, for each model and period, how many of the nine body–tail cutoffs reject the joint zero-alpha null at the 5% level. The 1960s row starts in January 1967, when the common sample begins. The 2020s row ends in December 2024.

Table 6.1: Calendar subperiod body–tail rejections

Period	Obs.	CAPM	FF3	Carhart	FF5	FF6	q5
1967–1969	727	0/9	0/9	0/9	0/9	1/9	4/9
1970–1979	2,526	0/9	0/9	0/9	0/9	0/9	2/9
1980–1989	2,528	0/9	3/9	2/9	5/9	5/9	9/9
1990–1999	2,528	0/9	4/9	0/9	0/9	0/9	0/9
2000–2009	2,515	4/9	0/9	1/9	2/9	3/9	4/9
2010–2019	2,516	0/9	0/9	0/9	0/9	0/9	0/9
2020–2024	1,258	0/9	3/9	3/9	0/9	0/9	0/9

Notes: Each entry reports the number of rejected joint zero-alpha tests among the nine body–tail split ratios. The sample is the common daily sample. HAC standard errors use 21 daily lags. Bold entries highlight q5 rejections.

The calendar results show two facts. First, body–tail rejection is not uniform over time. q5 rejects at all cutoffs in the 1980s. It does not reject in the 1990s, the 2010s, or 2020–2024. Second, other models also reject in some periods, but q5 has the highest average rejection frequency. Across the seven calendar subperiods, q5 rejects 30.2% of the joint tests on average. The other models range from 6.3% to 15.9%. The full-sample result is therefore not a single-period outlier. It is the average effect of internal pricing errors that become strong in particular historical periods.

6.2 Rolling 10-year windows

Calendar decades are easy to read, but their boundaries are arbitrary. I therefore repeat the test in rolling 10-year windows. I focus on 10-year windows to reduce short-window estimation noise and to detect persistent internal pricing errors. Table 6.2 summarizes 600 rolling windows with at least 2,000 common-sample daily observations.

Table 6.2: Rolling 10-year body–tail rejections

Model	Windows	Mean reject (%)	Median reject (%)	Any reject (%)
CAPM	600	8.1	0.0	15.0
FF3	600	14.4	0.0	38.3
Carhart	600	9.4	0.0	27.8
FF5	600	13.6	0.0	29.0
FF6	600	14.1	0.0	30.2
q5	600	40.1	44.4	79.0

Notes: The table summarizes 10-year rolling windows with at least 2,000 common-sample daily observations. Mean and median rejection shares are computed across the nine body–tail split ratios within each window. “Any rejection” is the share of rolling windows in which at least one split ratio rejects joint zero alpha at the 5% level. HAC standard errors use 21 daily lags.

The rolling-window results sharpen the contrast. q5 rejects 40.1% of the cutoffs on average, and its median rejection share is 44.4%. At least one cutoff rejects in 79.0% of the 10-year windows. By contrast, the mean rejection shares of CAPM, FF3, Carhart, FF5, and FF6 range from 8.1% to 14.4%. The q5 body–tail rejection is therefore not only a full-sample arithmetic effect. It appears more often and more persistently in rolling 10-year windows.

Table 6.3 groups the q5 rolling windows by ending decade. This shows when the q5 rejection is concentrated. The rejection is strongest in windows ending in the 1980s and 1990s. It weakens after the 2000s and almost disappears in windows ending in the 2020s. Thus, q5 does not fail in a time-invariant way. Its body–tail tension is concentrated in particular historical regimes.

Table 6.3: q5 rolling 10-year rejections by ending decade

Ending decade	Windows	Mean reject (%)	Median reject (%)	Any reject (%)
1970s	60	24.3	22.2	93.3
1980s	120	57.4	66.7	84.2
1990s	120	61.5	66.7	99.2
2000s	120	38.2	44.4	87.5
2010s	120	30.3	22.2	70.8
2020s	60	2.0	0.0	13.3

Notes: The table groups q5 rolling 10-year windows by the decade in which the rolling window ends. Rejection shares are computed across the nine body–tail split ratios. HAC standard errors use 21 daily lags.

6.3 Detected q5 regimes

I finally use the q5 rolling rejection signal to separate periods in which q5 rejection is concentrated from periods in which it is absent. This regime split is diagnostic. It is not an independent out-of-sample test. I use it as a descriptive chronology that shows where the full-sample q5 rejection comes from.

Table 6.4: Detected q5 regimes and model-level rejections

Detected regime	Obs.	CAPM	FF3	Carhart	FF5	FF6	q5
Nonreject 1967–1976	2,221	0/9	0/9	0/9	0/9	0/9	0/9
Reject 1976–1978	484	9/9	5/9	5/9	5/9	5/9	8/9
Nonreject 1978–1982	1,116	0/9	0/9	0/9	0/9	0/9	0/9
Reject 1982–1996	3,392	0/9	3/9	2/9	3/9	4/9	8/9
Nonreject 1996–2001	1,325	0/9	1/9	0/9	0/9	0/9	0/9
Reject 2001–2006	1,130	5/9	0/9	0/9	3/9	3/9	7/9
Nonreject 2006–2024	4,761	0/9	0/9	0/9	0/9	0/9	0/9

Notes: Entries report the number of rejected joint zero-alpha tests among the nine body–tail split ratios. The initial partial transition segment in 1967 contains only 169 common-sample observations and is omitted. Regimes are detected from the q5 rolling rejection signal and are used only as a descriptive chronology. HAC standard errors use 21 daily lags.

Table 6.4 shows that q5 rejection is concentrated in specific regimes. In q5 nonreject regimes, most models do not reject the body–tail null. q5 also passes at all cutoffs. In the 1982–1996 and 2001–2006 q5 reject regimes, q5 rejects at 8/9 and 7/9 cutoffs, respectively. Other models also reject in some of these periods, but q5 is the most frequent and persistent source of rejection. The 1982–1996 regime is especially clear. CAPM never rejects. The Fama–French models reject at only 3/9 to 4/9 cutoffs. q5 rejects at 8/9 cutoffs.

Taken together, the subperiod results support two conclusions. First, body–tail rejection is not a mechanical full-sample artifact. It appears across multiple calendar subperiods and rolling 10-year windows. Second, the rejection is not time-invariant. The q5 internal pricing error is strongest from the 1980s to the mid-2000s and becomes much weaker in recent data. The next section therefore does not ask whether q5 always fails. It asks which q5 components amplify the rejection in the market’s size-ranked internal structure.

7 Robustness and Diagnostics

This section asks whether the body–tail results come from the way I measure the market factor, or from nonmarket factor blocks inside the models. Unless noted otherwise, all diagnostic tables use Newey–West standard errors with 21 daily lags. I run three checks. First, I test whether the full-period q5 rejection is sensitive to the HAC lag. Second, I replace each model’s native market factor with my production market return, cMKT. Third, I remove or restrict factor blocks to identify which combinations amplify or reduce the body–tail rejection.

7.1 HAC-lag sensitivity

The baseline inference uses a Newey–West lag of 21 trading days. I first check whether the full-period q5 rejection is a borderline result driven by this lag choice. Table 7.1 reports the q5 joint zero-alpha p -values for the full-period size-ranked body–tail test across split ratios and HAC lags.

Table 7.1: q5 body–tail joint-test p -values across HAC lags

Split p	NW5	NW21	NW63	NW252
0.500	1.53×10^{-5}	3.30×10^{-5}	5.22×10^{-5}	7.80×10^{-6}
0.600	7.63×10^{-6}	2.57×10^{-5}	5.90×10^{-5}	2.53×10^{-5}
0.750	4.28×10^{-7}	2.40×10^{-6}	3.62×10^{-6}	7.46×10^{-7}
0.800	2.11×10^{-7}	1.21×10^{-6}	1.72×10^{-6}	5.10×10^{-7}
0.850	1.40×10^{-5}	6.25×10^{-5}	8.41×10^{-5}	2.17×10^{-5}
0.900	3.33×10^{-4}	0.001	0.001	8.02×10^{-4}
0.950	0.003	0.007	0.007	0.007
0.975	0.026	0.040	0.035	0.038
0.990	0.004	0.009	0.010	0.018

Notes: The table reports p -values for the q5 Wald test of joint zero alpha for the body and tail legs. Rows correspond to the nine full-period size-ranked split ratios. Columns vary the Newey–West HAC lag length. The common daily sample is 1967–2024.

Table 7.1 shows that the full-period q5 rejection is not sensitive to the HAC lag. The joint zero-alpha null is rejected at the 5% level for all nine split ratios not only with 21 lags, but also with 5, 63, and 252 lags. The largest p -value remains below 0.041. The q5 body–tail rejection is therefore not a marginal result caused by a particular short-run autocorrelation correction. It is a stable internal pricing error in the full-period size-ranked decomposition.

7.2 Replacing the market factor with cMKT

A direct concern is that the q5 body–tail rejection may arise because the q-factor market factor is not identical to my production market portfolio. I address this concern by replacing the native market factor in q5 and FF6 with cMKT. The cMKT factor is the same production market return that the body and tail legs reconstruct. The cMKT variants therefore test whether market-return measurement error or market-factor mismatch drives the results.

Table 7.2 compares native FF6 and q5 with the corresponding cMKT variants. For FF6, the conclusion is almost unchanged. Native FF6 rejects the joint zero-alpha null at none of the nine split ratios. cMKT–FF6 rejects at only one split ratio. For q5, replacing the market factor with cMKT does not remove the rejection. Native q5 and cMKT–q5 both reject at all nine split ratios. The average body and tail alphas also have similar signs and magnitudes across the two q5 specifications.

Table 7.2: Market-factor replacement and body–tail rejections

Model	Sample	Obs.	Joint reject	Median p_J	$\bar{\alpha}_A$ (bp/yr)	$\bar{\alpha}_B$ (bp/yr)	Sum reject
FF6	1963–2024	15481	0/9	0.567	-10.3	36.7	0/9
cMKT–FF6	1963–2024	15481	1/9	0.425	-9.9	38.3	1/9
q5	1967–2024	14598	9/9	< 0.001	-56.2	181.0	8/9
cMKT–q5	1967–2024	14598	9/9	< 0.001	-50.7	187.7	9/9

Notes: The table compares native market-factor models with cMKT variants over each model’s available sample. “Joint reject” counts the number of size cutoffs, out of nine, for which the Wald test of joint zero alpha rejects at the 5% level. “Sum reject” counts rejections for $\alpha_A + \alpha_B = 0$. Alphas are annualized basis points. HAC standard errors use 21 daily lags. Net-market p -values for cMKT variants are not reported because the net portfolio is spanned by construction, making residual-based p -values numerically degenerate.

This result makes a market-factor mismatch explanation difficult to sustain. Once I use cMKT, the aggregate market pricing error disappears by construction. The q5 body–tail rejection does not disappear. I therefore turn to the nonmarket factor blocks.

7.3 Factor-block ablation across model families

Table 7.3 summarizes selected factor-block ablations for each model family. Each model uses its native available sample. The table is not a cross-family horse race. It is a within-family diagnostic. It asks which blocks reduce or amplify the body–tail pricing errors.

In the traditional Fama–French family, the full specifications are broadly stable. FF5 and FF6 do not reject the joint zero-alpha null at any split ratio in their full specifications. Rejections increase when I remove SMB from FF5 or FF6. This suggests that the size factor works as a stabilizing block in the body–tail decomposition. It absorbs pricing errors between the large-cap body and the small-cap tail. Carhart is also stable in the full specification, but rejections increase sharply when HML is removed. q5 behaves differently. The MKT-only q5 variant does not produce body–tail rejections, but full q5 rejects at all nine split ratios. The q5 rejection therefore does not come from the market factor alone. It appears when the q5 nonmarket block is added.

Table 7.3: Selected factor-block ablations across model families

Family	Variant	Kept factors	Sample	Joint reject	Median p_J	$\bar{\alpha}_A$ (bp/yr)	$\bar{\alpha}_B$ (bp/yr)
FF3	Full FF3	MKT+SMB+HML	1926–2024	1/9	0.230	12.6	-7.6
	MKT only	MKT	1926–2024	2/9	0.103	-22.0	164.1

	MKT only	MKT	1967–2024	0/9	0.768	-18.9	81.5
	Drop EG	MKT+ME+IA+ROE	1967–2024	2/9	0.098	-26.8	106.6
	Drop ROE	MKT+ME+IA+EG	1967–2024	6/9	0.001	-51.0	151.8
	Drop ME	MKT+IA+ROE+EG	1967–2024	9/9	< 0.001	-143.7	629.1

Notes: The table reports selected ablations over model-specific native samples. “Joint reject” counts 5% Wald rejections across the nine body–tail split ratios. The table is intended as a within-family diagnostic rather than a cross-family sample-controlled horse race. HAC standard errors use 21 daily lags.

Two points matter. First, adding more factors does not mechanically reduce body–tail rejections. In some models, removing a factor increases rejections. In q5, however, the full

factor block produces the strongest rejection. Second, this pattern does not fit a simple market-beta measurement story. The q5 MKT-only variant passes. The problem appears in the q5-specific nonmarket block.

7.4 The ROE–EG block in q5

Table 7.4 examines q5 variants in more detail. MKT-only q5 does not reject at any split ratio. Adding ME also does not produce joint rejections. The same is true for MKT+ME+IA. In contrast, MKT+ME+ROE rejects at some split ratios, and MKT+ME+EG rejects at six of the nine split ratios. The leave-one-out results point in the same direction. Dropping EG reduces q5 rejections from nine to two. Dropping ROE still leaves six rejections. Replacing ROE with the Fama–French RMW factor also fails to remove the rejection when EG remains in the model.

Table 7.4: Native q5 factor-block diagnostics

Variant	Kept factors	Joint reject	Median p_J	$\bar{\alpha}_A$ (bp/yr)	$\bar{\alpha}_B$ (bp/yr)	Sum reject
Full q5	MKT+ME+IA+ROE+EG	9/9	< 0.001	-56.2	181.0	8/9
MKT only	MKT	0/9	0.768	-18.9	81.5	0/9
MKT+ME	MKT+ME	0/9	0.530	12.9	-77.3	4/9
MKT+ME+IA	MKT+ME+IA	0/9	0.429	11.2	-72.1	3/9
MKT+ME+ROE	MKT+ME+ROE	3/9	0.094	-27.0	110.1	4/9
MKT+ME+EG	MKT+ME+EG	6/9	0.008	-48.8	144.7	6/9
MKT+ME+RMW	MKT+ME+RMW	0/9	0.809	-3.7	-15.7	0/9
Drop EG	MKT+ME+IA+ROE	2/9	0.098	-26.8	106.6	5/9
Drop ROE	MKT+ME+IA+EG	6/9	0.001	-51.0	151.8	6/9
ROE to RMW	MKT+ME+IA+RMW+EG	8/9	< 0.001	-53.5	161.4	7/9

Notes: The table reports q5 ablations over 1967–2024. “Joint reject” and “Sum reject” count 5% rejections across the nine body–tail split ratios. Alphas are annualized basis points. HAC standard errors use 21 daily lags.

Table 7.5 repeats the same diagnostic with cMKT-based q5 variants. The conclusion is unchanged when I replace the market factor with cMKT. The cMKT+ME and cMKT+ME+IA variants are broadly stable. The cMKT+ME+EG variant produces strong rejections. The cMKT+ME+ROE variant also increases rejections, but less than the EG specification. A full specification that replaces ROE with RMW still fails to remove the body–tail rejection as long as EG remains in the model.

Table 7.5: cMKT q5 factor-block diagnostics

Variant	Kept factors	Joint reject	Median p_J	$\bar{\alpha}_A$ (bp/yr)	$\bar{\alpha}_B$ (bp/yr)	Sum reject
cMKT q5	cMKT+ME+IA+ROE+EG	9/9	< 0.001	-50.7	187.7	9/9
cMKT+ME	cMKT+ME	1/9	0.270	12.7	-76.9	3/9
cMKT+ME+IA	cMKT+ME+IA	1/9	0.247	11.6	-70.6	2/9
cMKT+ME+ROE	cMKT+ME+ROE	4/9	0.051	-24.9	113.0	6/9
cMKT+ME+EG	cMKT+ME+EG	7/9	0.002	-44.2	150.2	7/9
cMKT+ME+RMW	cMKT+ME+RMW	1/9	0.591	-2.2	-13.3	0/9
ROE to RMW	cMKT+ME+IA+RMW+EG	8/9	< 0.001	-47.9	168.3	8/9

Notes: The table reports cMKT q5 ablations over 1967–2024. The market factor is replaced by the production market return. Because the net market is mechanically spanned by cMKT, net-alpha p -values are not economically informative and are omitted. HAC standard errors use 21 daily lags.

Taken together, the q5 body–tail rejection is closely linked to the ROE–EG block, and especially to EG. It is not a q-market measurement error. ME appears to stabilize the model rather than destabilize it. Dropping ME makes the rejection stronger, while MKT+ME and MKT+ME+IA are broadly stable. The q5 body–tail failure is therefore not a simple lack-of-size-factor story. A more precise interpretation is that the q5 profitability–growth block leaves offsetting pricing errors on market components sorted by market-capitalization rank.

8 Discussion

8.1 Aggregate market fit and internal consistency

When I regress the market portfolio on a factor model that already contains a market factor, a small pricing error is not a demanding test. It is largely expected by construction. This is especially true when the market factor directly tracks a broad stock-market return, or when it is my production market return, cMKT. In these cases, the aggregate market zero-alpha condition is close to a definitional relation. It does not imply that the model prices the tradable components inside the market. The body–tail test keeps the aggregate relation intact and asks whether the zero-alpha condition also holds after I decompose the same market portfolio by its size-ranked structure.

The main result is that aggregate market pricing and internal market pricing are different conditions. The alpha of the aggregate market can hide the value-weighted average of internal leg alphas. If the body and tail have pricing errors with opposite signs, these errors can cancel in the aggregate market. This is what I find for q5. The alpha of the full market portfolio

is small and statistically insignificant. Yet the body–tail decomposition produces repeated negative alphas in the body leg and positive alphas in the tail leg. The body–tail test therefore does not restate the almost mechanical fact that a market-factor model fits the market return. It works as a stress test that reveals pricing errors hidden below aggregation.

This pattern is natural for an imperfect low-dimensional SDF approximation. A valid SDF must price all tradable assets at once. A linear factor model only approximates this object with a small set of factors. It can satisfy the pricing condition for an aggregate portfolio while leaving pricing errors in that portfolio’s components. The contribution here is to measure this possibility directly. The body and tail recombine to the same market portfolio. The test therefore studies internal pricing consistency without changing the aggregate asset being priced.

8.2 Maximum Sharpe ratio and zero-alpha criteria

This interpretation is consistent with the model-comparison logic of Barillas and Shanken. [Barillas and Shanken \(2017\)](#) argue that, for tradable factor models, the key question is whether one model spans the factors of another model in mean–variance space. Equivalently, the relevant object is the maximum attainable Sharpe ratio. [Barillas and Shanken \(2018\)](#) also compare candidate factors by the investment opportunity set that they provide. From this perspective, the ROE and EG factors in q5 may contain mean–variance information that is not captured by the Fama–French family. The spanning evidence in Section 4 is consistent with this possibility.

But the maximum-Sharpe-ratio criterion and the zero-alpha criterion for a given set of test assets are not the same empirical objective. If the true SDF prices every tradable asset in the same asset space, then zero alphas and no further Sharpe-ratio improvement are two expressions of the same pricing restriction. In empirical work, however, a factor model is only a restricted linear approximation. The researcher also chooses a specific set of test assets or a specific portfolio decomposition. In this setting, a factor can expand the mean–variance frontier and still leave pricing errors on externally given test assets.

The body–tail results fit this distinction. The q5-specific factors can be useful under spanning or maximum-Sharpe-ratio criteria. The same factor structure can still fail to price the body and tail of the market portfolio at the same time. In particular, the ROE–EG block may expand the investment opportunity set while also leaving opposite-signed leg-level alphas along the size-ranked market structure. The evidence does not reject the spanning criterion. It shows a separate dimension of pricing error that spanning alone does not reveal.

8.3 Split effects and the size-ranked structure

A natural concern is that the body–tail rejection may be caused by splitting the market into two legs, not by the size-ranked structure of the split. The random-split evidence makes this interpretation difficult. A random split keeps the same investible universe, split ratio, net market, sample period, factor model, and test statistic. It removes only the size-ranked assignment rule. Under q5, the body–tail test rejects the joint zero-alpha restriction at every split ratio. The matched random split has a rejection rate close to the nominal level.

The result is therefore not a mechanical statement that splitting the market always creates pricing errors. I can split the same market at the same ratios and largely remove the q5 rejection by randomizing the assignment rule. This contrast suggests that the body–tail pricing errors are tied to the size-ranked structure inside the market. The random split is not a structural null model in which the factor model is true. It is an empirical benchmark for the pricing errors created by the split itself. It supports the interpretation that the body–tail result is economically linked to size-ranked market decomposition.

Microstructure effects are another possible concern. The tail leg may be more exposed to nonsynchronous trading, price delay, and other frictions. These effects can affect daily beta and alpha estimates. They are unlikely to explain the full pattern. If nonsynchronous trading were the main driver, similar rejections should appear across other market-factor models that use the same tail leg. They do not. CAPM, Carhart, FF5, and FF6 are broadly stable in the full-period body–tail tests, while q5 rejects at all split ratios. The random splits also use the same universe and split ratios. They share much of the small-stock exposure and estimation uncertainty. Yet the q5 rejection falls toward the nominal level. Microstructure noise may add noise to tail returns, but it is not a sufficient explanation for the systematic q5 body–tail alpha pattern.

8.4 Interpreting the q5 evidence

This distinction is especially important for q5. I do not interpret the evidence as showing that q5 is generally inferior. The question is narrower. I ask whether the q5 factor structure prices the internal components of the market portfolio with zero alpha. This is different from asking whether q5 contains useful factors in mean–variance space.

The ablation results sharpen this point. The q5 rejection is unlikely to come from a mismatch between the q-factor market return and my production market return. When I replace the q5 market factor with cMKT, the net market is spanned by construction. The body–tail rejection remains almost unchanged. The MKT-only, MKT+ME, and MKT+ME+IA variants are also broadly stable. The rejection becomes stronger when ROE and EG enter

the model. Dropping EG substantially weakens the full q5 rejection. Dropping ROE leaves much of the rejection in place. Replacing ROE with RMW does not remove the rejection when EG remains.

The most conservative interpretation is that the q5 body–tail tension is closely related to the ROE–EG block, especially EG. This does not mean that EG is economically meaningless. EG may be one of the sources that distinguish q5 from the Fama–French models. The point is different. The same profitability–growth block that supplies distinctive return information can leave opposite-signed pricing errors when the market is decomposed by market-cap rank. In this sense, q5’s strength and its body–tail weakness may be two sides of the same factor structure.

8.5 Time variation and the recent weakening

The subperiod evidence shows that the q5 body–tail rejection is not a purely mechanical full-sample artifact. It also shows that the rejection is not constant over time. In rolling 10-year windows and detected regimes, q5 rejections are strong from the 1980s through the mid-2000s. They weaken sharply in the recent period. This pattern may be related to time variation in the ROE and EG factor premia, especially the EG premium.

The q5 factor returns are consistent with this interpretation. The EG premium is very strong in the 1980s and 1990s. Its annualized mean is about 12% in each decade, and its Newey–West t -statistics exceed 6. In 2020–2024, the annualized mean falls to about 3.6%, with a t -statistic of 0.63. ROE also has a positive long-run premium, but its recent statistical strength weakens. This change is directionally consistent with the decline in q5 body–tail rejections in recent rolling windows.

This interpretation should remain cautious. ROE and EG premia can be positive in some nonrejection periods. Rejection is not determined by factor means alone. Body–tail alpha reflects leg betas, the covariance structure of the factors, time variation in factor premia, and the way these premia load on the size-ranked market structure. The recent nonrejection period is therefore consistent with weaker ROE–EG premia, but it is not by itself a causal explanation.

8.6 Scope and limitations

The test is intentionally narrow. I study an investible market portfolio built from CRSP common stocks. I define body and tail legs by cumulative market capitalization. The results should therefore be read as a diagnostic for the internal size-ranked decomposition of the U.S. stock market. They are not a universal claim about all asset classes or all possible test-

asset designs. The split ratios, annual formation rule, delisting and dividend-reinvestment treatment, and HAC lag choices are all part of the empirical design. Random splits and cMKT robustness checks reduce the concern that the result is mechanical, but they do not prove invariance across all market decompositions.

The detected-regime analysis is also descriptive. It is based on the q5 rolling rejection signal. I use it to provide a chronology of when the q5 rejection appears. I do not treat it as an independent structural-break test. Likewise, the recent weakening of the ROE–EG premia is consistent with the weakening of body–tail rejections, but it is not the only possible explanation. Future work can study time-varying factor loadings, regime-dependent factor premia, and the dynamics of SDF pricing errors across internal market components more directly.

These limitations also suggest extensions. The body–tail split is only one way to dissect the market portfolio. I use cumulative market capitalization, but the same aggregation–decomposition logic can be applied to liquidity, turnover, dividend policy, profitability, investment, index membership, or institutional ownership. Some decompositions may reveal pricing errors that are hidden in the aggregate market. Others may make existing rejections disappear. The body–tail test is therefore both a result about size-ranked market decomposition and a starting point for a broader diagnostic framework.

Overall, the evidence shows that a factor model can price the aggregate market and still fail to price the components inside it. This does not deny the usefulness of existing factor models. It shows that aggregate market sanity checks miss an internal consistency dimension. The body–tail test measures this dimension in a simple and replicable way. Random splits and factor-block diagnostics show that the pricing errors are not merely split effects. They are linked to the size-ranked structure inside the market and to specific nonmarket factor blocks.

9 Conclusion

I study whether a factor model that prices the aggregate market also prices the market’s internal components. A small alpha for the market return is a weak test when the model already includes a market factor. I therefore keep the aggregate market relation intact and split the same CRSP investible market portfolio into body and tail legs by cumulative market capitalization. The two legs exactly recombine to the original market portfolio. The body–tail test is not a substitute for spanning or maximum Sharpe ratio comparisons. It is a complementary diagnostic for internal pricing consistency.

The evidence has four main parts. First, my CRSP-based production market return

passes the aggregate market sanity check. CAPM, FF3, Carhart, FF5, FF6, and q5 all deliver very high R^2 and small market-level alphas. Second, the body–tail decomposition reveals large model differences. q5 passes the aggregate market check, but it rejects the joint zero-alpha restriction at all nine split ratios in the full sample. The body leg repeatedly has negative alpha, while the tail leg repeatedly has positive alpha. These errors cancel when the two legs are recombined into the market. Third, matched random splits sharply weaken the rejection. The result is therefore not a mechanical consequence of splitting the market into two tradable legs. It is linked to the size-ranked structure inside the market. Fourth, the diagnostic tests point to q5’s ROE–EG block, especially EG. Replacing the q5 market factor with cMKT does not remove the rejection, while removing EG substantially weakens it.

I do not interpret these results as evidence that q5 is generally inferior. q5 may expand the mean–variance frontier and may perform well under spanning or maximum Sharpe ratio criteria. The point is narrower. In an imperfect low-dimensional SDF approximation, a factor can improve the attainable Sharpe ratio and still leave pricing errors on externally given test assets. The body–tail evidence shows that this can happen even inside the market portfolio itself. The same factor block that carries useful mean–variance information can leave offsetting pricing errors across the body and tail of the market.

The test is deliberately limited. I study U.S. CRSP common stocks, and I define the body and tail by cumulative market capitalization. The results should therefore be read as evidence on a size-ranked decomposition of the aggregate market, not as a universal statement about all assets or all possible decompositions. This narrow design is also what makes the test transparent. The two legs reconstruct the market, random splits control for the act of splitting, and cMKT substitutions separate market-factor measurement from nonmarket factor structure.

The broader lesson is simple. Pricing the aggregate market is a necessary sanity check, but it is not enough. The aggregate market can look priced because opposite errors inside the market cancel. Factor-model evaluation should therefore examine not only aggregate market fit, but also whether the model prices the market’s tradable internal components.
