

Aligning Network Equivariance with Data Symmetry: A Theoretical Framework and Adaptive Approach for Image Restoration*

Feiyu Tan[†], Qi Xie[‡], Zongben Xu[§], and Deyu Meng[¶]

Abstract. Image restoration is an inherently ill posed inverse problem. Equivariant networks that embed geometric symmetry priors can mitigate this ill posedness and improve performance. However, current understanding of the relationship between network equivariance and data symmetry remains largely heuristic. Particularly for real world data with imperfect symmetry, existing research lacks a systematic theoretical framework to quantify symmetry, select transformation groups, or evaluate model-data alignment. To bridge this gap, we conduct an analysis from an optimization perspective and formalize the intrinsic relationship among data symmetry priors, model equivariance, and generalization capability. Specifically, we propose for the first time a quantifiable definition of non strict symmetry at the dataset level (rather than sample level) and use it as a constraint to formulate the restoration inverse problem. We then show that the equivariance for restoration models can be naturally derived from this inverse problems incorporated the proposed symmetry constraints, and that the equivariance error of the optimal restoration operator is strictly bounded by the data symmetry error and the discretization mesh size. Furthermore, by analyzing the network’s empirical risk, we demonstrate that aligning equivariance with data symmetry optimizes the bias variance trade off, minimizing the total expected risk. Guided by these insights, we propose a Sample Adaptive Equivariant Network that uses a hypernetwork and transformation learnable equivariant convolutions to dynamically align with each sample’s inherent symmetry. Extensive experiments on super resolution, denoising (natural and remote sensing images), and deraining validate our theoretical findings and show significant superiority over standard baselines and traditional equivariant models. Our code is available at <https://github.com/tanfy929/SA-Conv>.

1. Introduction. Images serve as a crucial medium for information recording and transmission, where the quality affects the reliability of downstream tasks such as analysis, diagnosis, and further processing. However, the processes of acquisition, compression, and storage inevitably introduce various degradations, including noise, blur, and artifacts [28, 40]. Consequently, image restoration has emerged as a fundamental problem in computer vision, aiming to recover high-quality images from degraded observations [9, 46]. It holds great theoretical and practical value, which is essential for remote sensing, medical imaging, security surveillance, and heritage preservation [5, 32, 36, 53].

Mathematically, image restoration can be formulated as an ill-posed inverse problem [20,

[29, 39], where regularizations are usually introduced to mitigate the ill-posed issue. Formally, let $\hat{Y} \in \mathbb{R}^{m \times m}$ denote a degraded image, $K \in \mathbb{R}^{p \times p}$ be a blur kernel, and D represent an identity or down-sampling operator. The general single-image restoration problem can be formulated as:

$$(1.1) \quad Y^* = \arg \min_{X \in \tilde{\Omega}} \left(\min_K \|\hat{Y} - D(K * X)\|_F^2 \right) + \tilde{R}(X),$$

where $*$ denotes discrete spatial convolution, the feasible set $\tilde{\Omega}$ and regularization term $R(X)$ both encode the prior knowledge of the data, restricting the solution space to valid images. This formulation has laid the foundation for unsupervised image restoration and has played a key role over the past decade or so. Recently, it still provides a principled framework for the theoretical analysis of image processing, and has become one of the most standard formal cornerstones in image restoration theory [7, 54].

Rather than directly solving problem (1.1), data-driven deep learning strategies have been more widely adopted in recent years [10, 54]. Leveraging their powerful non-linear approximation capabilities, deep networks have significantly outperformed traditional methods across various tasks. Formally, let Ψ denote a deep network, the deep learning-based image restoration problem can be formulated as:

$$(1.2) \quad \Psi^* = \arg \min_{\Psi \in \Lambda} \frac{1}{N} \sum_{n=1}^N \|\hat{X}_n - \Psi(\hat{Y}_n)\|_F^2,$$

where $\{\hat{Y}_n, \hat{X}_n\}_{n=1}^N$ represents the paired training dataset, and Λ represents the hypothesis space of the network determined by the chosen neural network architecture. Despite their remarkable success, standard deep learning architectures still suffer from notable limitations. The most prominent issue is their black-box design, which makes them difficult to explicitly embed data priors (i.e., designing Λ). As a result, standard networks exhibit poor interpretability, and heavily rely on large-scale paired data.

Recently, equivariant network¹ [8, 44] has been widely recognized as an effective approach to explicitly embed geometric symmetry priors, which is one of the most intrinsic data prior. Its effectiveness has been extensively validated [8, 44, 50, 13]. The most representative example is the classical CNN architecture, whose convolutional operations perfectly realize translation equivariance, thereby improving parameter efficiency and model generalization, and achieving performance far superior to that of fully connected networks in image processing tasks. Inspired by CNNs, equivariant network structures incorporating more transformations, such as rotation, reflection, and scaling, have been successively proposed [8, 44], further demonstrating the advantages of equivariant design in specific scenarios [13, 50]. Such successes are often attributed to the explicit utilization of the corresponding geometric symmetry priors.

However, the current understanding of the relationship between network equivariance and data symmetry priors remains largely at a heuristic level, relying heavily on human intuition. In particular, for real-world data with imperfect symmetry, existing research lacks a systematic

¹The equivariance of a network requires that when the input undergoes a specific transformation, the internal feature layers and the final output undergo corresponding and predictable transformations.

Figure 1: Overview of the structure of this work. To address the limitations of existing works, Section 2 formulate a dataset-level, non-strict symmetry constraint and the associated restoration model. This forms the foundation for the analyses in Sections 3 and 4, which reveal that data symmetry governs operator equivariance and network empirical risk. These findings motivate the adaptive equivariant network design in Section 5, achieving better alignment between model equivariance and data symmetry and leading to improved performance.

theoretical framework to quantify data symmetry, select transformation groups, or formally evaluate the alignment between data characteristics ($\tilde{\Omega}$ and $\tilde{R}$) and network constraints (Λ). In this research line, the pioneering work [6] took an important step by theoretically analyzing the relationship between invariant regularizers ($\tilde{R}$) and equivariant proximal operators. Nevertheless, this conclusion relies on the assumption of an ideally invariant regularizer, which deviates from the practical need for expressive regularizers. Moreover, this work does not clarify the relationship between general network and the dataset, and thus offers limited guidance for designing equivariant networks. Furthermore, recent studies [30] have suggested that strict equivariance may not be optimal and that the embedded symmetry must align with the data itself. However, these studies still do not provide a mathematical definition of data symmetry, falling short of providing rigorous theoretical justifications. More fundamentally, prior works generally treat geometric symmetry as an inherent property of individual images and establish model based on this single-sample assumption. This perspective is inherently limited: an individual image rarely exhibits strict geometric symmetry, and enforcing constraints on isolated samples cannot exploit the rich inter-sample correlations that naturally exist across a dataset.

In summary, as shown in the left part of Fig. 1, existing approaches suffer from three key limitations. (I) Their consideration of symmetry is mainly grounded in single-sample modeling, which is misaligned with real-world data distributions (image samples are usually not symmetric). Moreover, its definition lacks quantifiability, making it difficult to formally evaluate the degree of symmetry and to theoretically analyze its relationship with model equivariance. (II) The sample-level consideration unavoidably results in a failure to leverage inter-sample information. (III) The selection of transformation groups remains heuristic, offering little principled guidance for network design.

To overcome these limitations, as outlined in right part of Fig. 1, we conduct a rigorous analysis for dataset symmetry, model the image restoration problem from a statistical,

dataset-level perspective and establish the intrinsic relationship among data symmetry and model equivariance. Specifically, we propose, for the first time, a quantifiable definition of non-strict symmetry at the dataset level, and utilize it as a dataset-level constraint to formulate the corresponding image restoration inverse problem. Theoretically, this formulation yields an optimal restoration operator, which represents the performance upper bound. Recognizing deep neural networks as universal function approximators, we further postulate that an adequately trained deep neural network effectively converges to this optimal restoration operator. Based on this insight, we show that the equivariance of restoration models can be naturally derived from the proposed dataset-constrained inverse problem. This allows us to quantify the equivariance error bound and further analyze the network’s empirical risk, thereby providing a solid theoretical foundation for general deep network design.

To avoid the comprehension difficulties caused by the complex technical approach described above, we provide a detailed illustration of the paper’s main structure, contributions, and the logical relationships among different sections, in Fig. 1. Please refer to it for a easy understanding. Overall, the main contributions of our work can be summarized as follows:

- **Theoretical Modeling of Data Symmetry and Operator Equivariance.** We construct a quantifiable symmetry metric for non-strict symmetry at the dataset level, which overcomes the inherent mismatch between single-sample modeling and real-world data distributions. By incorporating this metric as a constraint in the image restoration inverse problem, we mathematically formalize the intrinsic relationship between data symmetry and operator equivariance. Our proposed theorems establish that in the continuous domain, the equivariance error of the optimal restoration operator is bounded by the intrinsic dataset symmetry error (Theorem 3.3). When extended to the discrete domain, this error is jointly governed by the data symmetry error and the spatial discretization mesh size (Theorem 3.6).
- **Risk Analysis of Equivariant Network.** Based on the established equivariance properties of the optimal restoration operator, we further derive the empirical risk bound for equivariant networks (Theorem 4.2). Integrating this with classical generalization theories, we formulate the expected risk and explicitly establish the bias-variance trade-off. Crucially, we deduce a mathematical condition under which equivariant networks theoretically outperform the standard networks, which demonstrates that minimizing the dataset symmetry error through sample-adaptive transformations is imperative to optimize this trade-off and achieve lower expected risk.
- **Sample-Adaptive Network Design.** Based on our theoretical findings, we propose for the first time an equivariant network whose transformation group adapts to individual samples (Section 5). Specifically, we construct a class of parameterized transformation groups and innovatively employ a hypernetwork to predict the group parameters from each sample, thereby achieving adaptive adjustment of the transformation group. Furthermore, by feeding the adaptive group parameters into an equivariant network architecture built upon parameterized transformation groups [37], we can obtain a transformation-group-adaptive equivariant network. This mechanism can be plug-and-play integrated into existing convolutional architectures, maximizing the alignment between network equivariance and data symmetry, thus effectively reducing empirical risk while preserving generalization benefits.

- **Extensive Experimental Verification.** We evaluate our method on diverse tasks, including super-resolution and denoising for natural and remote sensing images, as well as single-image rain removal (Section 6). The proposed method consistently outperforms both standard baselines and traditional strict equivariant networks, validating the correctness and practical value of our theoretical framework.

The rest of paper is organized as follows. Section 2 establishes the mathematical formulation of the dataset symmetry and restoration problem. Section 3 analyzes the equivariance properties of the optimal restoration operator. Section 4 investigates the empirical risk and generalization of equivariant networks. Section 5 details the proposed sample-adaptive equivariant network. Finally, experiments are presented in Section 6.

2. Mathematical Modeling. In this section, we formulate image restoration for the first time as an inverse optimization problem at the dataset level, introduce dataset symmetry constraints, and associate it with a deep network trained on the same dataset. We start from introducing the continuous formulation of both traditional sample-level inverse problem and the proposed dataset-level one, treating digital images as discretely sampled instances of an underlying continuous physical signal. This framework allows us to analyze the problem at its source, effectively decoupling the intrinsic geometric properties of the solution from sampling artifacts. Subsequently, we extend this model to the discrete domain to reflect practical digital imaging processes. Furthermore, following the commonly adopted assumption that neural networks are universal approximators, we present a key hypothesis concerning the relationship between deep learning methods for image restoration and the optimization framework, thereby laying the foundation for the subsequent sections.

2.1. Continuous Problem Formulation on Single Sample. In the continuous domain, images are typically modeled as smooth functions defined on a continuous support. Consequently, for the image restoration problem, the degraded image and the blur kernel can be represented as functions $\hat{r} \in C^\infty(\mathbb{R}^2)$ and $k \in C^\infty(\mathbb{R}^2)$, respectively. Formally, let h denote the spatial mesh size, a digital image can be viewed as the spatial discretization of a smooth function at the cell-centers of a regular grid, thus we have:

$$(2.1) \quad \hat{r}(x_{ij}) = \hat{Y}_{ij}, \quad k(t_{uv}) = K_{uv},$$

where $x_{ij} = ((i - (m+1)/2)sh, (j - (m+1)/2)sh)^T$, $t_{uv} = ((u - (p+1)/2)h, (v - (p+1)/2)h)^T$, and s denote the downsampling rate of D in (1.1). If the image degradation process does not involve downsampling, we can simply set $s = 1$.

Then, the general restoration problem for a single image can be formulated as the following optimization task:

$$(2.2) \quad \Phi[\hat{r}] = \arg \min_{r \in \Omega} \left(\min_k \int_{\mathbb{R}^2} \left(\hat{r}(x) - \int_{\mathbb{R}^2} k(t)r(x-t)dt \right)^2 dx \right) + R[r],$$

where $\Phi[\hat{r}]$ denotes the restoration operator, $R[r]$ is the regularization functional, and the feasible set Ω constrain the space of valid image function.

2.2. Symmetry Constraints on Dataset Level. In formulation (2.2), the regularizer $R[r]$ and the feasible set Ω encode prior knowledge to restrict the solution space for a single sample. However, as discussed in Section 1, this sample-level approach inevitably results in a failure to exploit inter-sample correlations and an inability to overcome the fact that an individual image rarely exhibits ideal, strict geometric symmetry. Conversely, empirical observations suggest that the statistical distribution of local features exhibits strong symmetric properties across the entire dataset, yet a rigorous mathematical definition of this dataset-level symmetry has been absent in previous literature. In this section, we propose, for the first time, dataset-level symmetry metrics, which is expected to be significant for model generalization.

Consistent Symmetry Constraint. We first define the symmetry constraint for the image dataset $\{\hat{r}_n\}_{n=1}^N$ with respect to a single universal transformation group G . The corresponding symmetry set is defined as:

$$(2.3) \quad \Omega = \left\{ [r_1, r_2, \dots, r_N] \mid \sum_{n=1}^N R[r_n] = \sum_{n=1}^N R[\pi_A[r_n]], \forall A \in G \right\},$$

where π_A denotes the action of the transformation A on the image function, explicitly given by $\pi_A[r](x) = r(A^{-1}x), \forall x \in \mathbb{R}^2$. In the equation, we take the regularization functional $R[\cdot]$ of the image restoration problem (2.2) as the characteristic functional of symmetry. The constraint in (2.3) indicates that, as long as the sum (equivalent to the expectation) of the local feature quantity characterized by R over the entire dataset is invariant under a transformation, then we can say that the local feature is symmetric with respect to that characteristic functional and transformation at the dataset level. For the adaptability of this definition to real data (comparing with defining symmetry at single sample level), please refer to Fig. 2.

Adaptive Symmetry Constraint. The consistent symmetry constraint assumes that all images share the same transformation group G , which may still deviate considerably from real-world situations. For example, in image data, different samples are often captured from varying viewpoints, leading to different optimal symmetry transformation groups for different samples [37]. Therefore, we further generalize this to a scenario where each image is optimally aligned with a sample-specific transformation group. Formally, we define symmetry with respect to a family of transformation groups $\{G_n\}_{n=1}^N$ as follows²:

$$(2.4) \quad \Omega = \left\{ [r_1, r_2, \dots, r_N] \mid \sum_{n=1}^N R[r_n] = \sum_{n=1}^N R[\pi_{A_n}[r_n]], \forall A_n \in G_n \right\},$$

where G_n represents the transformation group for the n -th sample, and π_{A_n} denotes the corresponding sample-dependent group action. This relaxation permits the establishment of distinct, adaptive symmetries for individual samples, ensuring the model captures the rich, local symmetries inherent to natural images that captured under disparate perspectives. For the adaptability of this definition to real data, please refer to Fig. 2 and Table 1.

²Theoretically, the groups G_n can be arbitrary, as long as they all share the same cardinality $|G_n|$. In practice, however, G_n are usually designed to exhibit a highly consistent structure across different n , for avoiding the over fitting problem. In this work, we define G_n as the rotation group combined with a sample-adaptive affine transformation D_n . Consequently, the variation in G_n across different samples is governed entirely by three learnable affine parameters, as detailed in Section 5.

Relaxed Symmetry Constraint. Moreover, in practical applications, strict symmetry rarely holds. To accommodate this, we introduce a relaxed constraint set bounded by an error margin ε :

$$(2.5) \quad \Omega_\varepsilon = \left\{ [r_1, r_2, \dots, r_N] \mid \frac{1}{N} \left| \sum_{n=1}^N R[r_n] - \sum_{n=1}^N R[\pi_{A_n}[r_n]] \right| \leq \varepsilon, \forall A_n \in G_n \right\},$$

where $\varepsilon > 0$ quantifies the upper bound of the empirical data symmetry error.

In the remainder of this paper, we focus on solving the image restoration problem under this type of symmetry constraint, as it most faithfully reflects practical data distributions. As shown in Fig. 1, it serves as the fundamental premise of our theory, controlling the equivariance error bound of the optimal restoration operator, which will be derived in Section 3.

Remarks about the Proposed Constraint. Constructing an effective regularizer R is crucial for obtaining an optimal solution to image restoration inverse problems. Existing works have made significant progress in deriving model equivariance from the invariance of R [6]. However, such approaches typically require R to be strictly invariant for arbitrary image samples, which severely restricts the choice of valid regularizers and likely fails to meet the requirements of building an inverse problem that can yield an ideal solution. The proposed dataset-level formulation relaxes this restriction: it requires neither strict invariance of R nor perfect geometric symmetry of individual samples.

As a result, a broad class of common local feature extraction functions can readily satisfy the symmetry constraint in (2.5). In particular, even a complex R can satisfy this as long as it serves as a stable local feature descriptor regularizer. Since many such descriptors, especially convolution-based ones, are widely recognized as effective regularizers for inverse problems, satisfying the constraint does not conflict with the ability to drive the solution toward the ideal one. Hence, in theory, there always exists an R that reasonably satisfies the proposed symmetry constraint and drives the solution of the inverse problem sufficiently close to the ideal, providing a solid foundation for the subsequent theoretical analysis.

Furthermore, based on the relaxed symmetry constraint (2.5), we introduce a computable metric to explicitly quantify the degree of symmetry across a dataset in practice. Given a discretized transformation group $G_n = \{A_n^t\}_{t=1}^T$ and let $\mathcal{G} = \{G_n\}_{n=1}^N$, we define:

$$(2.6) \quad \varepsilon_{\mathcal{G}} = \max_t \left(\frac{1}{N} \left| \sum_{n=1}^N R[r_n] - \sum_{n=1}^N R[\pi_{A_n^t}[r_n]] \right| \right).$$

A smaller $\varepsilon_{\mathcal{G}}$ corresponds to a tighter error bound ε , indicating a stronger and more stable dataset-level geometric prior.

Symmetry Verification on Real Datasets. To empirically validate the rationality of proposed Ω_ε , we statistically evaluate how various commonly used regularizers R satisfy different symmetry constraints, measured by calculating the proposed symmetry metric $\varepsilon_{\mathcal{G}}$ on the widely used DIV2K dataset [1]. We compare three scenarios: (i) strict rotations on a single image (sample-level), (ii) strict rotations on the entire dataset (dataset-level), and (iii) adaptive transformations on the dataset (adaptive dataset-level). Detailed settings and numerical results are provided in Section 6.1.

Fig. 2(a) shows the histograms of the metric ε_G across three scenarios under five different regularizers R . A smaller ε_G indicates higher feature stability under transformations, meaning the metric fits the data well and captures its underlying symmetric structure. As observed, across all evaluated regularizers, the dataset-level constraints (blue bars) consistently yield lower error values than single-sample constraints (green bars), and the adaptive configuration (red bars) achieves the lowest values. This consistent results across R confirms that our framework does not depend on a specially designed regularizer, verifying its practical generality. Taking the TV operator as an example, Fig. 2(b) visualizes the line charts of three scenarios. The green curve fluctuates sharply, indicating that the single image cannot yield stable symmetry metric values (i.e., cannot provide reliable geometric priors), while the blue (consistent rotation on entire dataset) and red (adaptive transformations on dataset) curves both achieve more stable values. This highlights the importance of defining symmetry metric at the dataset level and the advantage of adaptive transformation groups.

Figure 2: (a) Histograms of the symmetry metric ε_G for three constraint scenarios under five different regularizers. (b) Take TV as an example, the local feature responses under varying rotation angles across three scenarios.

2.3. Restoration Model under Symmetry Constraint. Based on the established relaxed symmetry constraint, we formulate the corresponding restoration models in the continuous and discrete domains, respectively.

Continuous Problem Formulation. Building upon the dataset-dependent symmetry constraint Ω_ε , we can construct the optimal restoration model at the dataset level:

$$(2.7) \quad \{\Phi[\hat{r}_n]\}_{n=1}^N = \arg \min_{\{r_n\}_{n=1}^N \in \Omega_\varepsilon} \sum_{n=1}^N \left(\min_k \int_{\mathbb{R}^2} \left(\hat{r}_n(x) - \int_{\mathbb{R}^2} k(t) r_n(x-t) dt \right)^2 dx \right) + R[r_n],$$

where $\{r_n\}_{n=1}^N$ and $\{\Phi[\hat{r}_n]\}_{n=1}^N$ denote the tuples of the target functions and the corresponding restoration results, respectively, Φ denotes the restoration operator. It should be noted that, unlike traditional restoration operators based on a single sample, the proposed Φ takes into account cross-sample information to a certain extent, which well overcomes the two fundamental limitations of single-sample constrained model aforementioned, i.e., the inability to exploit inter-sample correlations across the entire dataset, and the lack of ideal geometric symmetry in a single natural image.

Discrete Problem Formulation. While the continuous formulation establishes a rigorous theoretical baseline, practical digital imaging inherently necessitates a discrete computational model. Consequently, we introduce the discrete restoration operator $\hat{\Phi}$. With the

discretization defined in (2.1), the dataset-level discrete restoration model is formulated as:

$$(2.8) \quad \{\tilde{\Phi}(\hat{Y}_n)\}_{n=1}^N = \arg \min_{\{Y_n\}_{n=1}^N \in \tilde{\Omega}_\varepsilon} \sum_{n=1}^N \min_K \|\hat{Y}_n - D(K * Y_n)\|_F^2 + \tilde{R}(Y_n),$$

where D is the downsampling operator and $\tilde{R}(\cdot)$ is the discrete counterpart of R , $\tilde{\Omega}_\varepsilon$ represents the feasible set for the problem:

$$(2.9) \quad \tilde{\Omega}_\varepsilon = \left\{ \{Y_n\}_{n=1}^N \mid \{r_n\}_{n=1}^N \in \Omega_\varepsilon \text{ and } (Y_n)_{ij} = r_n(x_{ij}), \forall n=1, 2, \dots, N, i, j=1, 2, \dots, m \right\}.$$

As shown in Fig. 1, the two constrained inverse problem established in (2.7) and (2.8) will enable us to quantify the equivariance properties of the optimal operator in Section 3.

2.4. Deep Learning Approximation for the Optimal Operator. While the discrete model formulated in (2.8) provides a mathematical definition of the image restoration task, directly solving this optimization problem via traditional iterative algorithms usually involves a high computational cost. Moreover, classical solvers heavily rely on hand-crafted regularizers, which struggle to fully capture the complex distributions of natural images. In contrast, recent studies have shown that data-driven deep learning methods can well avoid the aforementioned difficulties, and directly learn Ψ^* through the framework in (1.2).

Connection Assumption. Given the universal approximation capability of deep networks [2, 17], it is reasonable to assume that an adequately trained model effectively converges to the ideal image restoration operator. Besides, as discussed in the remarks about the proposed constraint, the solver of the inverse problem under the proposed symmetry constraint (i.e., in formulation (2.8)) can also be sufficiently close to the ideal image restoration operator. We formalize this as the following assumption.

Assumption 2.1 (Ideal Approximation). Consider a finite dataset $\{\hat{Y}_n, \hat{X}_n\}_{n=1}^N$, let $\tilde{\Phi}$ denote the restoration operator obtained from the dataset-level inverse model (2.8), and Ψ^* denote a image restoration deep network adequately trained on the given dataset via (1.2). We assume that both $\tilde{\Phi}$ and Ψ^* approximately converge to the ideal restoration operator learned from this dataset. Consequently, for any degraded sample $\hat{Y}_n$, there exists:

$$(2.10) \quad \|\tilde{\Phi}(\hat{Y}_n) - \Psi^*(\hat{Y}_n)\| \leq \eta,$$

where η is a constant close to 0.

This assumption bridges the optimization problem solution with modern deep learning practice. Building on this assumption and the equivariance properties of the inverse problem solver established in Section 3, we can further derive upper risk bounds for deep networks, as detailed in Section 4.

For conciseness and readability, we assume $\eta = 0$ in the derivation, meaning that both $\tilde{\Phi}$ and Ψ^* achieve the ideal restoration operator. This assumption is without loss of generality: if $\eta \neq 0$, one only needs to add η to the final conclusions.

Definition of Equivariant Network. When restricting the feasible region to a equivariant subset $\Lambda_{EQ} \subset \Lambda$:

$$(2.11) \quad \Lambda_{EQ} = \{\Psi \mid \Psi \in \Lambda, \Psi(\tilde{\pi}_{A_n}(\hat{Y}_n)) = \tilde{\pi}_{A_n}(\Psi(\hat{Y}_n)), \forall A_n \in G_n, n=1, 2, \dots, N\},$$

the deep learning framework (1.2) characterizes the training process of equivariant networks, where $\tilde{\pi}_{A_n}$ denotes the transformation acts in the discrete domain, which satisfies:

$$(2.12) \quad (\tilde{\pi}_{A_n}(\hat{Y}_n))_{ij} = \pi_{A_n}[\hat{r}_n](x_{ij}).$$

In this paper, we will investigate the properties of the learned equivariant result Ψ_{EQ}^* in this scenario. Specifically, we analyze its empirical and expected risks and provide a theoretical comparison against the standard optimal network Ψ^* .

It should be noted that in (2.11), the transformation group G_n may vary with different data indices n , this is because the objective of our study includes equivariant networks whose transformation group adapts to the data sample. In general, G_n is restricted to a single, fixed group for all samples, in which case our theoretical framework degenerates to previous network architectures.

3. Equivariance Analysis of Restoration Operator. In this section, we analyze the equivariance of the optimal restoration operators derived from the optimization problems in (2.7) and (2.8), establishing the relationship between the operator's equivariance and the intrinsic symmetry of the data.

3.1. Equivariance Analysis in Continuous Domain. To facilitate this analysis, we first provide the following lemmas³.

Lemma 3.1. *For continuous image functions $\hat{r}(x), r(x) \in C^\infty(\mathbb{R}^2)$, the following filter optimization:*

$$(3.1) \quad \varphi[\hat{r}, r] = \arg \min_k \int_{\mathbb{R}^2} \left(\hat{r}(x) - \int_{\mathbb{R}^2} k(t)r(x-t)dt \right)^2 dx,$$

with $k(t)$ being the filter function, satisfies $\pi_A[\varphi[\hat{r}, r]] = \varphi[\pi_A[\hat{r}], \pi_A[r]]$, where π_A denote how the transformation acts on images, i.e., $\pi_A[r](x) = r(A^{-1}x)$.

Lemma 3.2 (Norm-Preserving). *For a function $r(x) \in C^\infty(\mathbb{R}^2)$ and the transformation $A \in G$ satisfying $|\det(A)| = 1$, the L_2 norm is invariant under the group action π_A . That is:*

$$(3.2) \quad \|r(x)\|_2^2 = \|\pi_A[r](x)\|_2^2.$$

Based on these properties, we establish the main theorem concerning the equivariance of the restoration operator $\Phi[\cdot]$ in the continuous domain for the problem defined in (2.7).

Theorem 3.3 (Equivariance Error of Restoration Operator). *Consider a degraded image dataset $\{\hat{r}_n\}_{n=1}^N$ and the corresponding restoration problem defined in (2.7), $\Phi[\cdot]$ denotes the optimal restoration operator and Ω_ε is the feasible set defined under the relaxed symmetry constraint in (2.5). Assume the objective function satisfies the μ -quadratic growth condition in a local neighborhood of the optimal solution [4, 11], that is for*

$$(3.3) \quad F[r_n] = \min_k \int_{\mathbb{R}^2} \left(\hat{r}_n(x) - \int_{\mathbb{R}^2} k(t)r_n(x-t)dt \right)^2 dx + R[r_n],$$

³The proofs can be found in the supplementary material.

we have $\sum_{n=1}^N F[r_n] - F[r_n^*] \geq \mu \sum_{n=1}^N \|r_n - r_n^*\|_2^2$, where μ is a positive constant, $\{r_n^*\}_{n=1}^N$ is the solution of (2.7). Then, for $\forall A_n \in G_n, n = 1, 2, \dots, N$ with $|\det(A_n)| = 1$, the following equivariance error bound holds:

$$(3.4) \quad \frac{1}{N} \sum_{n=1}^N \|\Phi[\pi_{A_n}[\hat{r}_n]] - \pi_{A_n}[\Phi[\hat{r}_n]]\|_2^2 \leq \frac{2\varepsilon}{\mu},$$

where π_{A_n} denotes how the transformation A_n acts on image function, i.e., $\pi_{A_n}[r_n](x) = r_n(A_n^{-1}x), \forall x \in \mathbb{R}^2$.

Proof. By the definition of Φ , in (2.7), we have:

$$(3.5) \quad \begin{aligned} \{\Phi[\pi_{A_n}[\hat{r}_n]]\}_{n=1}^N &= \arg \min_{\{r_n\} \in \Omega_\varepsilon} \sum_{n=1}^N \left(\min_k \int_{\mathbb{R}^2} \left(\hat{r}_n(A_n^{-1}x) - \int_{\mathbb{R}^2} k(t) r_n(x-t) dt \right)^2 dx \right) + R[r_n] \\ &= \arg \min_{\{r_n\} \in \Omega_\varepsilon} \sum_{n=1}^N \left(\int_{\mathbb{R}^2} \left(\hat{r}_n(A_n^{-1}x) - \int_{\mathbb{R}^2} \varphi[\pi_{A_n}[\hat{r}_n], r_n](t) r_n(x-t) dt \right)^2 dx \right) + R[r_n], \end{aligned}$$

where $\varphi[\hat{r}, r]$ is the filter optimization operator defined in (3.1). Let $\bar{r}_n = \pi_{A_n}^{-1}[r_n]$, $\bar{t} = A_n^{-1}t$, and $\bar{x} = A_n^{-1}x$, and define $\pi_{A_n} \circ \{r_n\}_{n=1}^N = \{\pi_{A_n}[r_n]\}_{n=1}^N$. By Lemma 3.1, we have:

$$(3.6) \quad \begin{aligned} &\arg \min_{\{r_n\} \in \Omega_\varepsilon} \sum_{n=1}^N \left(\int_{\mathbb{R}^2} \left(\hat{r}_n(A_n^{-1}x) - \int_{\mathbb{R}^2} \varphi[\pi_{A_n}[\hat{r}_n], r_n](t) r_n(x-t) dt \right)^2 dx \right) + R[r_n] \\ &= \pi_{A_n} \circ \arg \min_{\{\bar{r}_n\} \in \Omega_\varepsilon} \sum_{n=1}^N \left(\int_{\mathbb{R}^2} \left(\hat{r}_n(A_n^{-1}x) - \int_{\mathbb{R}^2} \varphi[\pi_{A_n}[\hat{r}_n], \pi_{A_n}[\bar{r}_n]](t) \bar{r}_n(A_n^{-1}(x-t)) dt \right)^2 dx \right) + R[\pi_{A_n}[\bar{r}_n]] \\ &= \pi_{A_n} \circ \arg \min_{\{\bar{r}_n\} \in \Omega_\varepsilon} \sum_{n=1}^N \left(\int_{\mathbb{R}^2} \left(\hat{r}_n(A_n^{-1}x) - \int_{\mathbb{R}^2} \pi_{A_n}[\varphi[\hat{r}_n, \bar{r}_n]](t) \bar{r}_n(A_n^{-1}(x-t)) dt \right)^2 dx \right) + R[\pi_{A_n}[\bar{r}_n]] \\ &= \pi_{A_n} \circ \arg \min_{\{\bar{r}_n\} \in \Omega_\varepsilon} \sum_{n=1}^N \left(\int_{\mathbb{R}^2} \left(\hat{r}_n(\bar{x}) - \int_{\mathbb{R}^2} \varphi[\hat{r}_n, \bar{r}_n](\bar{t}) \bar{r}_n(\bar{x} - \bar{t}) d\bar{t} \right)^2 d\bar{x} \right) + R[\pi_{A_n}[\bar{r}_n]] \\ &= \pi_{A_n} \circ \arg \min_{\{\bar{r}_n\} \in \Omega_\varepsilon} \sum_{n=1}^N F[\bar{r}_n] + \sum_{n=1}^N (R[\pi_{A_n}[\bar{r}_n]] - R[\bar{r}_n]). \end{aligned}$$

Thus, we have:

$$(3.7) \quad \{\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]\}_{n=1}^N = \arg \min_{\{\bar{r}_n\} \in \Omega_\varepsilon} \sum_{n=1}^N F[\bar{r}_n] + \sum_{n=1}^N (R[\pi_{A_n}[\bar{r}_n]] - R[\bar{r}_n]).$$

By the definition of ‘arg min’, substituting $\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]$ into the objective function of the

above method and combining it with the optimality condition of $\Phi[\hat{r}_n]$, we obtain:

$$\begin{aligned}
 (3.8) \quad & \sum_{n=1}^N F[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] + \sum_{n=1}^N (R[\pi_{A_n}[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] - R[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]]) \\
 & \leq \sum_{n=1}^N F[\Phi[\hat{r}_n]] + \sum_{n=1}^N (R[\pi_{A_n}[\Phi[\hat{r}_n]]] - R[\Phi[\hat{r}_n]]).
 \end{aligned}$$

Then we get:

$$\begin{aligned}
 (3.9) \quad & \sum_{n=1}^N F[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] - F[\Phi[\hat{r}_n]] \\
 & \leq \sum_{n=1}^N (R[\pi_{A_n}[\Phi[\hat{r}_n]]] - R[\Phi[\hat{r}_n]]) - \sum_{n=1}^N (R[\pi_{A_n}[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] - R[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]]) \\
 & \leq \left| \sum_{n=1}^N (R[\pi_{A_n}[\Phi[\hat{r}_n]]] - R[\Phi[\hat{r}_n]]) \right| + \left| \sum_{n=1}^N (R[\pi_{A_n}[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] - R[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]]) \right| \\
 & \leq N\varepsilon + N\varepsilon = 2N\varepsilon.
 \end{aligned}$$

Since $[\Phi[\hat{r}_n]]$ and $[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] \in \Omega_\varepsilon$ satisfy the relaxed symmetry constraint defined in (2.5), the final inequality can thus be derived.

Since $\Phi[\hat{r}_n] = r_n^*$, with μ -quadratic growth condition and the norm invariance under the transformation π_{A_n} stated in Lemma 3.2, we have:

$$\begin{aligned}
 (3.10) \quad & \frac{1}{N} \sum_{n=1}^N \|\Phi[\pi_{A_n}[\hat{r}_n]] - \pi_{A_n}[\Phi[\hat{r}_n]]\|_2^2 = \frac{1}{N} \sum_{n=1}^N \|\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]] - \Phi[\hat{r}_n]\|_2^2 \\
 & \leq \frac{1}{N\mu} \sum_{n=1}^N F[\pi_{A_n}^{-1}[\Phi[\pi_{A_n}[\hat{r}_n]]]] - F[\Phi[\hat{r}_n]] \leq \frac{2\varepsilon}{\mu}.
 \end{aligned}$$

The proof is completed. ■

In summary, Theorem 3.3 establishes that in the continuous domain, the equivariance of the optimal solution is intrinsically governed by the data symmetry. Specifically, the equivariance error of the restoration operator is upper bounded by the data symmetry error ε . It should be noted that, the quadratic growth condition is only required to hold within a small ε -neighborhood of the optimal solution, making it easily satisfiable in practice.

3.2. Equivariance Analysis in Discrete Domain. While the continuous domain analysis provides fundamental theoretical results, practical applications inevitably involve discretization. To extend our conclusions to the discrete domain, it is imperative to account for errors introduced during the discretization process.

We first present the following important lemmas, which provides an upper bound on the discretization error between the continuous integral formulation and its corresponding discrete Riemann sum. The detailed proofs are provided in the supplementary material.

Lemma 3.4 (Discretization Error [50]). *Let $f \in C^2(\mathbb{R}^2)$ be a smooth function with a compact support bounded by a radius $D > 0$ (i.e., $f(x) = 0$ for $\|x\| \geq D$). If its second-order partial derivatives are globally bounded by a constant $C > 0$:*

$$(3.11) \quad \max \left\{ \left| \frac{\partial^2 f(x)}{\partial x_1^2} \right|, \left| \frac{\partial^2 f(x)}{\partial x_2^2} \right| \right\} \leq C, \quad \forall x \in \mathbb{R}^2,$$

then we have:

$$(3.12) \quad \left| \int_{\mathbb{R}^2} f(x) dx - \sum_{(i,j) \in \Delta} f(x_{ij}) h^2 \right| \leq CD^2 h^2,$$

where h is the mesh size, $\Delta = \{(i, j) \mid 1 \leq i, j \leq n\}$, $n = 2D/h + 1$, and x_{ij} are the corresponding regular grid coordinates.

Lemma 3.5 (Discretization Error of Regularization Term). *Consider a convolution-based local feature regularization functional R defined in the continuous domain as:*

$$(3.13) \quad \frac{1}{(D_r + D_R)^2} \int_{\mathbb{R}^2} \int_{\mathbb{R}^2} k^R(x) r(x - y) dx dy,$$

where $r(x)$ is the input image function and k^R is a convolution kernel function, with D_r and D_R being the bound of their compact support, respectively, i.e., $r(x) = 0$ for all $\|x\| \geq D_r$, and $k^R(x) = 0$ for all $\|x\| \geq D_R$. The discretization of R , denoted as $\tilde{R}$, is in the following formulation:

$$(3.14) \quad \frac{1}{(D_r + D_R)^2} \sum_{(i,j) \in \Delta} \sum_{(\hat{i}, \hat{j}) \in \Delta} k^R(x_{ij}) r(x_{i-\hat{i}, j-\hat{j}}) h^4,$$

where $h > 0$ is the mesh size, $\Delta = \{(i, j) \mid 1 \leq i, j \leq n\}$, $n = 2(D_r + D_R)/h + 1$, and x_{ij} are the corresponding regular grid coordinates. Furthermore, assume $r(x)$, $k^R(x)$, and their gradient and Hessian matrix are bounded, i.e., $\|r(x)\| \leq F_r$, $\|k^R(x)\| \leq F_k$, $\|\nabla r(x)\| \leq G_r$, $\|\nabla k^R(x)\| \leq G_k$, $\|\nabla^2 r(x)\| \leq H_r$, $\|\nabla^2 k^R(x)\| \leq H_k$. Then the discretization error satisfies:

$$(3.15) \quad |R - \tilde{R}| \leq (H_k F_r + 2G_r G_k + 2F_k H_r)(D_r + D_R)^2 h^2.$$

It should be noted that, in the subsequent theoretical analysis, we assume that the regularizers R and $\tilde{R}$ take the convolution-based forms specified in (3.13) and (3.14). This assumption is made without loss of generality: the specific choice of the regularizers affects only the constant factors in the discretization error and does not compromise the generality of our theoretical results. Indeed, the analysis requires only the boundedness of the first and second derivatives of the regularization terms. Moreover, convolution-based regularizers are among the most widely used in practice, which makes our choice sufficiently representative.

With the discretization error rigorously bounded, we are now able to establish the equivariance error bound for the optimal restoration operator in the discrete domain. The final conclusion is summarized in the following theorem.

Theorem 3.6 (Equivariance Error of Discrete Operator). *Consider the image restoration problem defined in (2.8) with feasible set $\tilde{\Omega}_\varepsilon$ (2.9) and observed dataset $\{\hat{Y}_n\}_{n=1}^N$. Let Y_n , K and $\tilde{\Phi}[\cdot]$ represents the restored image, the blur kernel, and the optimal restoration operator, respectively. Assume $\hat{r}(x), r(x), k(x)$ and R are the underlying continuous functions for discrete variables $\hat{Y}_n, Y_n, K$ and $\tilde{R}$ (3.14), respectively, where R is defined in the formulation of (3.13) with kernel function $k^R(x)$, the objective function (3.3) satisfies the μ -quadratic growth condition in a local neighborhood (the same as in Theorem 3.3), and the underlying functions satisfy the following support and boundedness conditions:*

$$(3.16) \quad \begin{aligned} & |\hat{r}(x)|, |r(x)| \leq F_1, \quad |k(x)| \leq F_2, \quad |k^R(x)| \leq F_3, \\ & \|\nabla \hat{r}(x)\|, \|\nabla r(x)\| \leq G_1, \quad \|\nabla k(x)\| \leq G_2, \quad \|\nabla k^R(x)\| \leq G_3, \\ & \|\nabla^2 \hat{r}(x)\|, \|\nabla^2 r(x)\| \leq H_1, \quad \|\nabla^2 k(x)\| \leq H_2, \quad \|\nabla^2 k^R(x)\| \leq H_3, \\ & \forall \|x\| \geq D_r, \quad \hat{r}(x) = 0 \text{ and } r(x) = 0, \quad \forall \|x\| \geq D_k, \quad k(x) = 0, \quad \forall \|x\| \geq D_R, \quad k^R(x) = 0, \end{aligned}$$

where ∇ and ∇^2 denotes the operators of gradient and Hessian matrix, respectively. Then, for any transformation $A_n \in G_n$ with $|\det(A_n)| = 1$, the equivariance error measured in the discrete Frobenius norm satisfies:

$$(3.17) \quad \frac{1}{N} \sum_{n=1}^N \left\| \tilde{\Phi}(\tilde{\pi}_{A_n}(\hat{Y}_n)) - \tilde{\pi}_{A_n}(\tilde{\Phi}(\hat{Y}_n)) \right\|_F^2 \leq Ch^2 + \hat{C}\varepsilon,$$

where $\tilde{\pi}_{A_n}$ denotes how the transformation A_n acts on image $\hat{Y}_n$, and $h > 0$ is the discretization mesh size as defined in (2.1). The constant terms involved are as follows: $C = C_1(D_r + D_R)^2 + C_2(D_r + D_k)^2$, $C_1 = \frac{4}{\mu}(H_3F_1 + 2G_1G_3 + 2F_3H_1)$, $C_2 = \frac{4}{\mu}\bar{C} + 8G_1^2 + 8F_1H_1$, $\bar{C} = 2(1 + 4D_k^2F_2)[4C_0D_k^2F_1 + (G_1^2 + F_1H_1)(1 + 4D_k^2F_2)s^2]$, $C_0 = F_1H_2 + F_2H_1 + 2G_1G_2$, and $\hat{C} = \frac{2}{\mu}$, s is the downsampling rate as defined in (2.1).

Proof Sketch. The objective is to generalize the continuous domain equivariance error bound to the practical discrete formulation. The proof proceeds by decomposing the total discrete equivariance error into two primary components: the continuous equivariance error and the discretization error. The former is directly bounded utilizing the conclusion of Theorem 3.3, while the latter is systematically bounded by applying Lemma 3.4 and Lemma 3.5 to bridge the continuous integrals with their discrete Riemann sums. Due to space constraints and the extensive length of the mathematical derivation, the complete proof is provided in the supplementary material. ■

Theorem 3.6 indicates that the optimal restoration operator maintains robust equivariance in the discrete domain corresponding to practical applications. Its equivariance error is strictly upper-bounded by a controllable limit that depends on the discretization mesh size h and the intrinsic data symmetry error ε . Consequently, as the image resolution increases and the dataset symmetry improves, the equivariance error asymptotically approaches zero.

4. Risk and Generalization Analysis for Equivariant Networks.

4.1. Empirical Risk of Equivariant Networks. The analysis in the above sections establishes the inherent equivariance of the restoration operator $\tilde{\Phi}$ achieved from the dataset-level

inverse model. This crucial finding provides a compelling justification for employing equivariant networks to approximate this operator. In this section, we investigate the empirical risk of equivariant networks, aiming to explore the factors that influence it.

Consider a training dataset $D_N = \{\hat{X}_n, \hat{Y}_n \mid n = 1, 2, \dots, N\}$, where $\hat{X}_n$ and $\hat{Y}_n$ represent the paired high quality ground truth and degraded observations, respectively. The empirical risk $\mathcal{L}_{emp}$ of a deep network Ψ is defined as:

$$(4.1) \quad \mathcal{L}_{emp}(\Psi) = \frac{1}{N} \sum_{n=1}^N \|\hat{X}_n - \Psi(\hat{Y}_n)\|_F^2.$$

Then the training of equivariant networks is to achieve $\Psi_{EQ}^* = \arg \min_{\Psi \in \Lambda_{EQ}} \mathcal{L}_{emp}(\Psi)$, where Λ_{EQ} is defined in (2.11). Before presenting our final conclusion, we first provide the following preliminary conclusion⁴.

Lemma 4.1 ([31]). *For any mapping Ψ , let $\bar{\Psi} = \sum_{A \in G} \frac{1}{|G|} \pi_A [\Psi[\pi_A^{-1}]]$, where G is the transformation group and π_A denotes how the transformation A acts on image, then $\bar{\Psi}$ is equivariant with respect to G , in the sense that for any $\bar{A} \in G$ and input image Y :*

$$(4.2) \quad \bar{\Psi}(\pi_{\bar{A}}(Y)) = \pi_{\bar{A}}(\bar{\Psi}(Y)).$$

Given the universal approximation capability of over-parameterized deep networks and the above conclusion, it can be easily seen that $\forall \Psi \in \Lambda$, $\bar{\Psi}$ is equivariant, i.e., $\bar{\Psi} \in \Lambda_{EQ}$.

Theorem 4.2 (Empirical Risk of Equivariant Network). *Consider the image restoration problem defined in (2.8) with feasible set $\tilde{\Omega}_\epsilon$ (2.5) and observed dataset $\{\hat{Y}_n\}_{n=1}^N$. Let Y_n , K and $\tilde{\Phi}[\cdot]$ represents the restored image, the blur kernel, and the optimal restoration operator, respectively. Assume $\hat{r}(x), r(x), k(x)$ and R are the underlying continuous functions for discrete variables $\hat{Y}_n, Y_n, K$ and $\hat{R}$ (3.14), respectively, where R is defined in the formulation of (3.13) with kernel function $k^R(x)$, the objective function (3.3) satisfies the μ -quadratic growth condition in a local neighborhood (the same as in Theorem 3.3), and the underlying functions satisfy the following support and boundedness conditions:*

$$(4.3) \quad \begin{aligned} &|\hat{r}(x)|, |r(x)| \leq F_1, \quad |k(x)| \leq F_2, \quad |k^R(x)| \leq F_3, \\ &\|\nabla \hat{r}(x)\|, \|\nabla r(x)\| \leq G_1, \quad \|\nabla k(x)\| \leq G_2, \quad \|\nabla k^R(x)\| \leq G_3, \\ &\|\nabla^2 \hat{r}(x)\|, \|\nabla^2 r(x)\| \leq H_1, \quad \|\nabla^2 k(x)\| \leq H_2, \quad \|\nabla^2 k^R(x)\| \leq H_3, \\ &\forall \|x\| \geq D_r, \quad \hat{r}(x) = 0 \text{ and } r(x) = 0, \quad \forall \|x\| \geq D_k, \quad k(x) = 0, \quad \forall \|x\| \geq D_R, \quad k^R(x) = 0, \end{aligned}$$

where ∇ and ∇^2 denotes the operators of gradient and Hessian matrix, respectively, and $h > 0$ is the discretization mesh size. Then, their empirical risks satisfy the following result:

$$(4.4) \quad \mathcal{L}_{emp}(\Psi_{EQ}^*) \leq 2\mathcal{L}_{emp}(\Psi^*) + \mathbf{C}h^2 + \hat{\mathbf{C}}\epsilon,$$

where $\Psi^* \in \Lambda$ and $\Psi_{EQ}^* \in \Lambda_{EQ}$ denote the adequately trained standard and equivariant networks, respectively, as defined in Section 2.4, $\mathbf{C} = 2C$ and $\hat{\mathbf{C}} = \frac{4}{\mu}$, the constant C are defined the same as Theorem 3.6.

⁴The proof of Lemma 4.1 is provided in the supplementary material.

Proof. The empirical risk of an adequately trained equivariant network Ψ_{EQ}^* can be expressed as:

$$(4.5) \quad \mathcal{L}_{emp}(\Psi_{EQ}^*) = \min_{\Psi_{EQ} \in \Lambda_{EQ}} \frac{1}{N} \sum_{n=1}^N \|X_n - \Psi_{EQ}(\hat{Y}_n)\|_F^2.$$

Applying the algebraic inequality for the squared Frobenius norm, i.e., $\|a - b\|_F^2 \leq 2\|a - c\|_F^2 + 2\|c - b\|_F^2$, we can obtain:

$$(4.6) \quad \begin{aligned} \mathcal{L}_{emp}(\Psi_{EQ}^*) &\leq \min_{\Psi_{EQ} \in \Lambda_{EQ}} \frac{2}{N} \sum_{n=1}^N \|X_n - \Psi^*(\hat{Y}_n)\|_F^2 + \frac{2}{N} \sum_{n=1}^N \|\Psi^*(\hat{Y}_n) - \Psi_{EQ}(\hat{Y}_n)\|_F^2 \\ &= \min_{\Psi_{EQ} \in \Lambda_{EQ}} \frac{2}{N} \sum_{n=1}^N \|\Psi^*(\hat{Y}_n) - \Psi_{EQ}(\hat{Y}_n)\|_F^2 + 2\mathcal{L}_{emp}(\Psi^*). \end{aligned}$$

According to Lemma 4.1 and the definition of the equivariant space (2.11), the projection of standard network Ψ via the Reynolds operator, defined as $\bar{\Psi} = \sum_{A_n \in G_n} \frac{1}{|G_n|} \pi_{A_n} [\Psi[\pi_{A_n}^{-1}]]$ is guaranteed to be a valid equivariant model (i.e., $\bar{\Psi} \in \Lambda_{EQ}$). Since the minimum risk over Λ_{EQ} must be less than or equal to the risk evaluated at any specific candidate within that space, then we can establish:

$$(4.7) \quad \begin{aligned} \mathcal{L}_{emp}(\Psi_{EQ}^*) &\leq \min_{\Psi_{EQ} \in \Lambda_{EQ}} \frac{2}{N} \sum_{n=1}^N \|\Psi^*(\hat{Y}_n) - \Psi_{EQ}(\hat{Y}_n)\|_F^2 + 2\mathcal{L}_{emp}(\Psi^*) \\ &\leq \frac{2}{N} \sum_{n=1}^N \left\| \Psi^*(\hat{Y}_n) - \sum_{A_n \in G_n} \frac{1}{|G_n|} \pi_{A_n} [\Psi^*[\pi_{A_n}^{-1}]] (\hat{Y}_n) \right\|_F^2 + 2\mathcal{L}_{emp}(\Psi^*). \end{aligned}$$

We apply Jensen's inequality utilizing the convexity of the squared norm to move the averaging summation outside:

$$(4.8) \quad \mathcal{L}_{emp}(\Psi_{EQ}^*) \leq \frac{2}{N} \sum_{n=1}^N \sum_{A_n \in G_n} \frac{1}{|G_n|} \left\| \Psi^*(\hat{Y}_n) - \pi_{A_n} [\Psi^*[\pi_{A_n}^{-1}]] (\hat{Y}_n) \right\|_F^2 + 2\mathcal{L}_{emp}(\Psi^*).$$

Let $\tilde{Y}_n = \pi_{A_n}^{-1} \hat{Y}_n$. Combining Theorem 3.6 and Assumption 2.1, we establish a connection between the network training process and the theoretical restoration solution analyzed in Section 3, thereby deriving the following conclusion:

$$(4.9) \quad \begin{aligned} \mathcal{L}_{emp}(\Psi_{EQ}^*) &\leq \frac{2}{N} \sum_{n=1}^N \sum_{A_n \in G_n} \frac{1}{|G_n|} \left\| \Psi^*[\pi_{A_n}[\tilde{Y}_n]] - \pi_{A_n}[\Psi^*[\tilde{Y}_n]] \right\|_F^2 + 2\mathcal{L}_{emp}(\Psi^*) \\ &\leq \frac{2}{N} \sum_{n=1}^N \sum_{A_n \in G_n} \frac{1}{|G_n|} (Ch^2 + \hat{C}\varepsilon) + 2\mathcal{L}_{emp}(\Psi^*) \leq 2(Ch^2 + \hat{C}\varepsilon) + 2\mathcal{L}_{emp}(\Psi^*). \end{aligned}$$

By defining $\mathbf{C} = 2C$ and $\hat{\mathbf{C}} = 2\hat{C}$, the proof is completed. ■

Theorem 4.2 indicates that the empirical risk of the equivariant network depends on the intrinsic data symmetry error ε , which originates from the relaxed symmetry constraint $\frac{1}{N} \left| \sum_{n=1}^N R[r_n] - \sum_{n=1}^N R[\pi_{A_n}[r_n]] \right| \leq \varepsilon$. Consequently, applying a consistent dataset-level transformation π_A to all samples often yields a large symmetry mismatch error ε , leading to a high empirical risk. In contrast, introducing a sample-adaptive transformation π_{A_n} via a hypernetwork allows the model to dynamically minimize this dataset symmetry error. This design enhances model flexibility and is expected to improve performance, particularly when handling complex images in real-world scenarios.

4.2. Generalization Theory of Equivariant Networks. While empirical risk measures the fitting error on training data, the ultimate metric of a model’s efficacy is its expected risk on unseen data. The generalization gap quantifies this critical discrepancy. Formally, for a deep network Ψ trained on the dataset D_N , the generalization error is typically defined as [19]:

$$(4.10) \quad GE(\Psi, D_N) = \mathcal{L}_{exp}(\Psi) - \mathcal{L}_{emp}(\Psi, D_N).$$

where $\mathcal{L}_{emp}$ denotes the empirical risk, and $\mathcal{L}_{exp}$ represents the expected risk associated with the unknown true data distribution.

For equivariant networks, embedding symmetry constraints restricts the hypothesis space, thereby reducing the generalization error. Sannai et al. [34] formally quantified this benefit by deriving a generalization bound via quotient feature spaces:

Lemma 4.3 (Theorem 3 in [34]). *Consider the equivariant deep neural networks Ψ_{EQ} , for any $\delta > 0$, there exists constant $\tilde{C} > 0$ that are independent of the input dimension d , the sample size N , and δ . The following inequality holds with probability at least $1 - 2\delta$:*

$$(4.11) \quad GE(\Psi_{EQ}) \leq \sqrt{\frac{\tilde{C}}{tN^{2/d}}} + \sqrt{\frac{2\log(1/\delta)}{N}},$$

where t denotes the size of the stabilizer subgroup. The second term arises from McDiarmid’s inequality [26], is a standard confidence penalty.

Lemma 4.3 provides an upper bound on the generalization error, which mainly depends on the size of the stabilizer subgroup t . For a standard, non-equivariant network Ψ , no geometric symmetries are enforced, meaning $t = 1$. Consequently, its generalization error bound reduces to:

$$(4.12) \quad GE(\Psi) \leq \sqrt{\frac{\tilde{C}}{N^{2/d}}} + \sqrt{\frac{2\log(1/\delta)}{N}}.$$

Comparing Lemma 4.3 and (4.12) reveals that equivariant networks effectively reduce the volume of the feature space that the model needs to explore by a factor of $\frac{1}{\sqrt{t}}$, thereby significantly enhancing the generalization capability.

The Bias-Variance Trade-off. The total expected performance of a model is bounded by the sum of its empirical risk (Bias) and generalization error (Variance). By combining

empirical risk bound (Theorem 4.2) with the generalization bound (Lemma 4.3), we can derive the expected risk upper bound for the optimal equivariant network Ψ_{EQ}^* :

$$(4.13) \quad \mathcal{L}_{\text{exp}}(\Psi_{EQ}^*) \leq 2\mathcal{L}_{\text{emp}}(\Psi^*) + \mathbf{C}h^2 + \hat{\mathbf{C}}\varepsilon + \sqrt{\frac{\tilde{\mathbf{C}}}{tN^{2/d}}} + \sqrt{\frac{2\log(1/\delta)}{N}}.$$

Correspondingly, the expected risk bound for the optimal standard network Ψ^* is:

$$(4.14) \quad \mathcal{L}_{\text{exp}}(\Psi^*) \leq \mathcal{L}_{\text{emp}}(\Psi^*) + \sqrt{\frac{\tilde{\mathbf{C}}}{N^{2/d}}} + \sqrt{\frac{2\log(1/\delta)}{N}}.$$

By comparing (4.13) and (4.14), we deduce that an equivariant network will theoretically guarantee a lower expected risk than a standard network if the following condition is satisfied:

$$(4.15) \quad \varepsilon < \frac{1}{\hat{\mathbf{C}}} \left(\sqrt{\frac{\tilde{\mathbf{C}}}{N^{2/d}}} \left(1 - \frac{1}{\sqrt{t}} \right) - \mathcal{L}_{\text{emp}}(\Psi^*) - \mathbf{C}h^2 \right).$$

This conclusion indicates that increasing the left term leads to a decline in the performance of equivariant networks. Therefore, enforcing a consistent transformation group on diverse real-world datasets is not optimal, since the symmetry error ε under a consistent group would be larger in this case (as shown in Fig. 2). It is thus imperative to design an adaptive network that dynamically aligns its geometric constraints with the data, keeping ε minimized.

Remark. It is worth noting that the mathematical assumptions required by our theoretical framework are highly practical. The μ -quadratic growth condition is only required to hold in a local neighborhood of the optimal solution, rather than globally across the entire highly non-convex landscape, which is easy to be satisfied by typical regularized inverse problems. The boundedness and regularity conditions in (4.3) essentially require the underlying continuous signals and operators to be sufficiently smooth and finite. Since real-world images are captured by band-limited optical sensors with a finite dynamic range, these assumptions inherently align with physical reality. Therefore, our theoretical bounds provide a rigorous yet realistic foundation for the subsequent adaptive network design.

5. Network Design Based on Theoretical Guidance. The theoretical framework established in Section 4 (particularly, Theorem 4.2) shows that the empirical risk of an equivariant model is bounded by the data symmetry error ε . However, as demonstrated in Fig. 2, using a single consistent transformation group for the entire dataset often leads to suboptimal dataset symmetry error, whereas a sample-adaptive transformation group family $\{G_n\}_{n=1}^N$ can significantly reduce this error. Therefore, a sample-adaptive transformation group family is expected to achieve a better trade-off between bias and variance.

Inspired by this, we propose a novel transformation-group sample-adaptive equivariant network framework in the following sections.

5.1. Adaptive Transformation Group Family and Filter Parametrization. We first introduce the following transformation-group-parameterized equivariant convolution framework [37], which is started by constructing the following learnable transformation group:

$$(5.1) \quad G_w = \{D_w A D_w^{-1}\},$$

where $A = \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix}$ is the rotation matrix, D_w is a learnable affine matrix defined as:

$$(5.2) \quad D_w = \begin{bmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{bmatrix} \begin{bmatrix} s_x & 0 \\ 0 & s_y \end{bmatrix} = \begin{bmatrix} s_x \cos \alpha & s_y \sin \alpha \\ -s_x \sin \alpha & s_y \cos \alpha \end{bmatrix},$$

where $w = [\alpha, s_x, s_y]$ denotes additive parameters, with s_x and s_y represent adaptive scaling factors along two orthogonal axes, and α determines the principal orientation.

Then, the transformation learnable filter φ can be achieved by further adopting the following filter parametrization framework [35, 45, 50]:

$$(5.3) \quad \varphi(A^{-1} D_w^{-1} x) = \sum_{k=1}^K v_k \varphi_k(A^{-1} D_w^{-1} x),$$

where v_k is the k -th learnable coefficient, which is a learnable parameter in the deep network.

5.2. Transformation Adaptive Equivariant Convolutions. Consequently, the transformation adaptive equivariant convolution framework can be constructed with filter in the framework (5.3). Specifically, taking construction of the learnable input layer of equivariant convolution as an example [37, 50], the convolution operation Ψ_w , which maps an input $r \in C^\infty(\mathbb{R}^2)$ to a feature map, can be formulated as:

$$(5.4) \quad \Psi_w[r](x, A) = \int_{\mathbb{R}^2} \varphi_{in}(A^{-1} D_w^{-1} \delta) r(x - \delta) d\sigma(\delta),$$

where σ is the measure on $\mathbb{R}^2$, A denotes the rotation transformation, which is also the index of group dimension, D_w is the adaptive transformation defined in (5.2), and φ_{in} is the parameterized filter as defined in (5.3). Under this framework, we can conveniently achieve sample-level adaptive adjustment of the transformation group by adjusting w for each sample.

This formulation can be readily generalized to the intermediate and output layers of the equivariant convolution framework, and their discretization can be easily performed following the strategy of previous work [37, 50]. Due to space constraints, we do not elaborate on the details of the intermediate layers, output layers, or the discretization in the main text. Interested readers are referred to the supplementary material, while a conceptual overview of the complete adaptive equivariant architecture is provided in Fig. 3(c).

5.3. Sample-Adaptive Symmetry via Hypernetwork. To achieve the sample-adaptive transformation, we introduce a hypernetwork for predicting w_n in the transformation adaptive equivariant convolutions, as illustrated in Fig. 3(b). Specifically, we follow the local image information extraction architecture proposed in prior work [12], for designing this hypernetwork. The input $\hat{Y}_n$ is first converted to grayscale, and a lightweight convolutional encoder is

Figure 3: Illustration of (a) adaptive transformation group family and filter parametrization; (b) the hypernetwork framework; (c) transformation adaptive equivariant convolutions.

then adopted to extract local features, which is in the shape of $c \times H \times W$, with c denotes the channel number. After this, both the extracted feature map and the grayscale input are first flattened along the spatial dimensions, which are in shape $c \times HW$ and $HW \times 1$, respectively. Perform matrix multiplication on the above expanded contents and divide by HW to achieve weighted local feature extraction [12]. Then the output c -dimensional vector is finally mapped into the 3-dimensional transformation parameter $w_n = [\alpha_n, s_{x_n}, s_{y_n}]$, through a MLP.

To ensure numerical stability and optimal convergence, we adopt a two-stage training strategy. First, the equivariant restoration backbone is pre-trained with w_n as a shared learnable parameter across all samples, initialized to $[0, 1, 1]$. Then, it is integrated with a hypernetwork to adaptively adjust w_n for each sample during end-to-end training.

6. Experimental Results. This section validates our theoretical framework through a systematic series of experiments. We first quantitatively verify the proposed dataset-level symmetry, which forms the mathematical cornerstone of our modeling. Subsequently, we evaluate the proposed Sample-Adaptive Equivariant Network across diverse image restoration tasks, including super-resolution, denoising (in both natural and remote sensing domains), and single-image deraining.

6.1. Empirical Validation of Dataset Symmetry. In Section 2.2, we introduce the definition of symmetry on dataset level and the relaxed symmetry constraint that better aligns with real-world data scenarios. Before presenting the restoration results, we detail the experimental settings and quantitative results for the empirical validation of dataset-level symmetry.

Experimental Setup. We conduct the analysis on the DIV2K dataset [1], evaluating

Figure 4: The process of feature extraction from images using classical differential kernels.

Table 1: Quantitative evaluation of data symmetry under various regularizers. The reported values denote the empirical symmetry metric $\varepsilon_{\mathcal{G}}$ (defined in (2.6)), where a lower value indicates stronger dataset-level symmetry.

Configuration		TV	Second-order TV	Sobel	Laplacian	Prewitt
Data	Trans.					
sample	strict	0.19	0.90	1.33	3.33	0.40
dataset	strict	0.04	0.60	0.32	2.18	0.18
dataset	adaptive	0.01	0.18	0.15	0.48	0.04

data symmetry using the metric $\varepsilon_{\mathcal{G}}$ defined in (2.6), which rigorously quantifies the maximum absolute deviation of the dataset-averaged local features under geometric transformations.

Without loss of generality, we adopt several widely used convolution-based feature extractors as R , including the TV operator, second-order TV, Sobel, Laplacian, and Prewitt filters. The discrete form $R[\pi_{A_n^t}[r_n]]$ can be efficiently calculated via the process illustrated in Fig.4⁵.

In practice, we sample the continuous rotation group at 32 uniformly discrete angles (i.e., $t = 32$ with a step size $\frac{\pi}{16}$) and quantitatively compare data symmetry under three scenarios: (i) Strict symmetry of single image: As the baseline case, we randomly select a single image and apply strict rotation transformation A^t to it, i.e., $\pi_{A^t}[r]$. (ii) Strict symmetry of entire dataset: We apply the identical strict rotations A^t to every sample r_n in dataset $\mathcal{D}$. This setting examines global statistical invariance under a consistent dataset-level group action. (iii) Adaptive symmetry of entire dataset: We apply a sample-adaptive transformation for each sample, i.e. $\pi_{A_n^t}[r_n]$, where $A_n^t \in G_{w_n}$ and the transformation group family is $\mathcal{G} = \{G_{w_n}\}_{n=1}^N$, with G_w defined in (5.1).

It is worth noting that scenario (iii) requires optimizing the affine parameters w_n for each sample, which necessitates a well-defined loss function. Although it is natural to directly use $\varepsilon_{\mathcal{G}}$ as the optimization objective, minimizing a function that contains a non-smooth max operator is numerically unstable. Therefore, we instead optimize w_n via gradient descent by minimizing the variance of the feature responses across different rotation angles. This continuously differentiable proxy effectively suppresses overall feature fluctuations, thereby tightly bounding the maximum deviation $\varepsilon_{\mathcal{G}}$.

As shown in Table 1, for various R , the dataset-level $\varepsilon_{\mathcal{G}}$ is consistently and significantly smaller than the single-sample one, and the adaptive-transformation $\varepsilon_{\mathcal{G}}$ is even lower than that under strict transformations. This confirms the rationality and generality of the proposed dataset-level symmetry metric: defining symmetry at the dataset level with adaptive

⁵It can be mathematically proven that $R[\pi_{A_n}[r_n]] = \int_{\mathbb{R}^2} \int_{\mathbb{R}^2} \varphi(A_n^{-1}x) r_n(y-x) dx dy, \forall A_n \in G_n$. Please refer to [37] for detailed proofs.

transformations aligns better with real-world scenarios for most regularizers.

6.2. Image Super-Resolution. Single image super-resolution (SR) aims to reconstruct high-resolution images from low-resolution observations, a fundamental task requiring the accurate recovery of high-frequency details.

Network Architecture Settings. Following Xie et al. [50], we evaluate the $\times 2$ scale SR task using three existing baselines, including EDSR [23], RDN [56], and RCAN [55]. To assess the impact of equivariant structures, we compare the proposed transformation sample-adaptive equivariant network against a standard CNN baseline and a comprehensive set of equivariant methods, including G-CNN [8], E2-CNN [44], Har-Net [47], PDO-eConv [35], F-Conv [50], B-Conv [49], and TL-Conv [37]. In each experiment, the standard convolution operators are replaced by their respective equivariant counterparts. For the G-CNN-based network, which is restricted to the $p4$ group ($k\pi/2$ rotations, $k = 1, 2, 3, 4$), we reduce the number of channels in each residual block to $1/4$ of the original network to maintain comparable memory costs. For the other equivariant methods, including SA-Conv, we employ the $p8$ group

to capture richer symmetries and set the channel number as $1/8$ to the original networks in each layer to keep memory consumption similar.

Datasets and Training Settings. To validate the generalization and robustness of the proposed method across diverse visual domains, we conduct experiments on two distinct types of imagery. For natural images, following previous works [23, 56, 55, 50], models are trained on 900 images from the DIV2K dataset [38] and tested on four benchmarks, including Urban100 [18], B100 [25], Set14 [52], and Set5 [3]. For remote sensing images, we use the RSSCN7 dataset [27, 57] to assess the method’s effectiveness on overhead images exhibiting

arbitrary orientations. It contains 2,800 images distributed across seven categories, each with four different scale images of 400×400 pixels collected by various sensors under different weather conditions. We randomly split the data into 2,600 training and 200 testing images.

All models are trained using the Adam optimizer on an NVIDIA RTX 4090 GPU. Following the original settings, we set the batch size to 16 for all networks. The training patch sizes are set to 64×64 for RDN based methods and 96×96 for EDSR and RCAN variants. Performance is quantified using PSNR and SSIM.

Quantitative and Qualitative Comparison. Table 2 and 3 presents the $\times 2$ SR results on natural images and remote sensing images, respectively. It can be observed that the proposed SA-Conv consistently achieves superior results compared to the competing methods in these two experiments. Notably, on the detail-rich natural image dataset Urban100, SA-Conv (EDSR) outperforms the baseline CNN by 0.503 dB in PSNR, and surpasses the transformation learnable equivariant convolution TL-Conv (not sample-adaptive) by 0.119 dB. SA-Conv (RCAN) achieves the best PSNR among all methods, reaching 32.803 dB. Similarly, on remote sensing images, SA-Conv (RDN) exceeds TL-Conv by 0.076 dB, while SA-Conv (RCAN) significantly outperforms the baseline CNN with a PSNR gain of 0.322 dB.

Visual comparisons are provided in Fig.5 and Fig.6 (take RCAN-based methods as an example). Standard baselines and strict equivariant methods tend to produce aliasing artifacts or over-smoothed textures in complex repetitive patterns. In contrast, SA-Conv reconstructs sharper edges and more faithful geometric details, effectively mitigating structural distortions.

6.3. Image Denoising. Image denoising is a classic restoration task that aims to remove noise from corrupted observations while preserving high-frequency structures.

Network Architecture Settings. Adhering to prior works [13], we adopt a unified ResNet architecture as the common backbone for all competing methods. Specifically, the backbone is configured with 16 residual blocks, each containing 256 channels. We evaluate the proposed SA-Conv against the standard CNN and multiple equivariant methods, including G-CNN [8], E2-CNN [44], Har-Net [47], PDO-eConv [35], F-Conv [50], B-Conv [49], and TL-Conv [37]. Consistent with SR configuration, we apply identical channel reduction strategies to ensure strictly comparable memory overhead across all models.

Figure 7: Visual results of Denoising from various methods on img039 of Urban100.

Figure 8: Visual results of Denoising from various methods on img046 of Ada4DIR.

Datasets and Training Settings. For natural image denoising, models are trained on 900 DIV2K samples [38] with Gaussian noise ($\sigma = 50$) and evaluated on Urban100 [18], B100 [25], Set14 [52], and Set5 [3] benchmarks. For remote sensing, we adopt the Ada4DIR denoising subset [22] (5,130 training and 270 testing images), where the noise standard deviations are randomly sampled from [5, 35]. Training hyperparameters remain consistent with the SR task, utilizing 48×48 cropped patches.

Quantitative and Qualitative Comparison. Table 4 shows the denoising performance on natural image benchmarks. Consistent with SR, most equivariant methods demonstrate superior noise suppression compared to the standard CNN baseline. Overall, SA-Conv achieves the best performance among all architectures, reaching 31.155 dB. These results once again demonstrate that equivariant networks can achieve performance gains over standard CNNs. When sample-adaptive transformations are further introduced to better align network equivariance with data symmetry, the performance advantage becomes more pronounced. The visualization results in Fig. 7 show that the proposed

Table 5: The denoising results of different competing methods on Ada4DIR dataset [22].

Method	Ada4DIR-Denoising [22]		#Param.
	PSNR	SSIM	
CNN	37.021	0.8999	19.49M
G-CNN[8]	37.042	0.8999	4.73M
E2CNN[45]	37.016	0.8993	3.00M
Har-Net[47]	36.998	0.8989	3.94M
PDO-eConv[35]	36.687	0.8935	2.37M
F-Conv[50]	37.046	0.8998	6.56M
B-Conv[49]	37.064	0.9009	6.56M
TL-Conv[37]	37.073	0.9013	6.56M
SA-Conv	37.104	0.9016	6.60M

method is able to preserve richer detail features. Similarly, for the remote sensing denoising task (Table 5), where noise levels vary substantially, SA-Conv still achieves the best performance (37.104 dB). As illustrated in Fig. 8, while competing methods often struggle to balance noise removal and texture preservation, thereby blurring fine details, SA-Conv produces noticeably cleaner images.

6.4. Single Image Rain Removal. To further verify the generalizability of our method, we extend our evaluation to single image rain removal, a task that requires eliminating rain streaks while preserving scene details.

Network Architecture Settings. We adopt RCDNet [41], a state-of-the-art deep unfolding network, as our baseline. RCDNet unfolds the iterative proximal gradient descent algorithm, employing learnable proximal operators (implemented via ResNet) to jointly estimate rain features and the clean background. Since natural scenes often exhibit rich symmetric structures, introducing equivariance into the background estimation module can help preserve such structural features. We construct equivariant variants of RCDNet by replacing the standard convolutions in the proximal operators with several state-of-the-art equivariant convolutions: F-Conv [50], B-Conv [49], TL-Conv [37], and the proposed SA-Conv. All equivariant models adopt the $p8$ group and reduce channel number to $1/8$ of the original network to maintain comparable memory usage.

Datasets and Training Settings. Experiments are conducted on the widely used Rain100L benchmark [51], which is the synthesized data set with one type of rain streaks. To ensure a rigorous comparison, all training settings and loss functions remain consistent with the original RCDNet.

Quantitative and Qualitative Comparison. As shown in Table 6, the baseline RCDNet is already a high-performance model (PSNR with 40.00 dB). Integrating symmetry priors into the background estimation module steadily improves performance. Notably, the proposed SA-RCDNet achieves the best PSNR of 40.54 dB, surpassing the original RCDNet and TLEQ-RCDNet by 0.57 dB and 0.18 dB, respectively. Visual results in Fig. 9 demonstrate that SA-RCDNet eliminates rain streaks more completely. While competing models may erase background details, our method faithfully preserves the structural integrity of the rain-free scene, validating the benefit of adaptive symmetry in background estimation.

Table 6: The rain removal results of different competing methods on Rain100L [51].

Method	Rain100L [51]	
	PSNR	SSIM
Input	26.90	0.8384
DSC[24]	27.34	0.8494
JCAS[16]	28.54	0.8524
Clear[14]	30.24	0.9344
DDN[15]	32.38	0.9258
RESCAN[21]	38.52	0.9812
PReNet[33]	37.45	0.9790
SPANet[42]	35.33	0.9694
JORDER_E[51]	38.59	0.9834
SIRR[43]	32.37	0.9258
IDT[48]	35.42	0.9674
RCDNet[41]	40.00	0.9860
FConv-RCDNet [50]	40.28	0.9867
BConv-RCDNet [49]	40.25	0.9863
TLEQ-RCDNet [37]	40.36	0.9869
SA-RCDNet	40.54	0.9873

6.5. Discussion. It is worth noting that: (i) In all experiments, TL-Conv, as an equivariant network, also learns its transformations, but it can only learn a consistent transformation

Figure 9: Visual results of Rain removal from various methods on img024 of Rain100L.

group for the entire dataset. It is easy to see that under such learnable transformations, the data symmetry is stronger than that under strict rotation transformations, yet weaker than that under the proposed sample-adaptive transformations. Consequently, the results of $\text{SA-Conv} > \text{TL-Conv} > \text{other methods}$, as observed across all the above experiments, is fully consistent with the proposed theoretical conclusions. (ii) Moreover, we can also observe that most equivariant methods (G-CNN, F-Conv, B-Conv) outperform CNN baselines across all backbones. This aligns with our conclusion: on datasets with strong symmetry, equivariant networks lead to improved performance.

7. Conclusions. In this paper, we establish a novel mathematical framework to formally analyze the relationship between data symmetry and network equivariance. By recognizing the fundamental limitations of defining symmetry on a single sample, we define, for the first time, symmetry at the dataset level, which naturally leads to the dataset-constrained restoration inverse problem. Through the analysis of this inverse problem, we prove that the optimal solution operator for image restoration should satisfy approximate equivariance, i.e., its equivariance error is bounded by both the intrinsic data symmetry error and the discretization mesh size. Moreover, through expected risk analysis, we demonstrate that aligning the model’s equivariance with data symmetry leads to improved performance.

This conclusion not only explains the source of the advantage of equivariant networks, but also highlights the importance of selecting the transformation group. It also explains why traditional convolutional networks outperform fully connected networks in image processing tasks: the perfect translation symmetry of images aligns with the translation equivariance of CNNs, allowing CNNs to significantly reduce generalization error without incurring approxi-

mation error.

Guided by these theoretical results, we propose the Sample-Adaptive Equivariant Network. By employing a hypernetwork to predict sample-specific parameters for transformation-learnable equivariant convolutions, our architecture dynamically adapts its geometric constraints to individual inputs. This mechanism minimizes the symmetry error while preserving generalization benefits. Extensive experiments across diverse tasks confirm the validity of our theoretical framework and demonstrate the significant superiority of the proposed method.

In the future, we aim to generalize our theoretical framework beyond continuous spatial transformations in the Euclidean domain. A highly promising direction is extending this symmetry-aware analysis to non-Euclidean manifolds and topological spaces, facilitating restoration tasks for graphs, point clouds, and complex physical systems governed by partial differential equations. Ultimately, we seek to establish a unified, symmetry-driven variational theory that accommodates abstract transformation groups and complex degradation mechanisms across diverse data modalities.
