

Plug, Play, and Comply: A Modular Framework for Online Variable Impedance with Arbitrarily Oriented Compliance Axes

Mihael Simonić¹ and Xiaocong Li^{1,2,*}

Abstract—The paper proposes a robot-agnostic compliant-control framework that extends the ROS control ecosystem with standardized joint and Cartesian command interfaces. It addresses a key limitation of existing control software: the lack of reusable infrastructure for implementing compliant-control algorithms across different manipulators while preserving a common interface to higher-level applications. A plugin-based architecture separates controller infrastructure from control-law implementation. Generic wrappers use existing hardware abstractions to interface with different manipulators, while runtime-loaded plugins implement only the control law. Command interfaces support updates of joint- and Cartesian-space references, stiffness and damping gains, nullspace targets, and feedforward terms, enabling variable impedance and diverse compliant-control formulations. Robot kinematics and dynamics are computed from URDF models using Pinocchio. The architecture facilitates the development of compliant-control strategies and enables the same implementation to be deployed across platforms unchanged. The complete framework, including reference controllers, high-level task interfaces, and example configurations for various manipulators, is available as open-source software. The reference Cartesian impedance controller supports task-dependent compliance by rotating translational and rotational stiffness and damping matrices, allowing the principal compliance directions to be updated online according to local task geometry rather than remaining fixed in the robot base or TCP frame. This is particularly important in contact-rich manipulation, where the desired directions of motion, constraints, and compliance directions may vary continuously throughout task execution. Real-robot experiments demonstrate task-dependent compliance in contact-rich manipulation, while simulations show portability across manipulators with distinct kinematic and dynamic characteristics. I. INTRODUCTION

Robot manipulation systems increasingly integrate high-level task generation with low-level execution. For example, VLA models expand the diversity of semantic commands that must be reliably grounded in physical robot behavior [1]. Likewise, learning-based policy execution and teleoperation systems benefit from compliant low-level interfaces that accommodate environmental uncertainty and human input [2]. Residual human-correction methods and shared autonomy frameworks similarly depend on stable and predictable contact behavior to ensure effective interaction [3].

These systems often produce low-frequency action chunks, task-level corrections, or semantic motion objectives at abstrac-

Fig. 1. Overview of the proposed plugin-based compliant-control framework. Standardized Cartesian or joint command messages expose motion references, stiffness and damping gains, and optional nullspace or feedforward parameters through the same interface. The wrapper-plugin separation decouples ROS deployment from the control-law implementation, while URDF-backed model terms support robot-agnostic execution across hardware and simulation.

tion levels that differ substantially from those of the underlying control loop. The low-level controller must therefore translate sparse or coarse commands into smooth, stable, and physically consistent motion. More fundamentally, it determines how high-level decisions are realized as forces, motions, and compliant behavior during physical interaction [4].

Recent work suggests that controller gains can influence the performance of imitation learning, reinforcement learning, and sim-to-real transfer [5]. VLA-based systems have also begun generating context-dependent stiffness and damping alongside motion commands for safer contact-rich execution [6]. This motivates exposing compliance parameters as explicit online commands rather than fixing them through nominal task assumptions or hiding them inside robot-specific controllers. The importance of this execution layer becomes particularly evident in contact-rich manipulation. Such tasks involve nonlinear and highly sensitive interactions with the environment and commonly require direct or indirect force-control methods, including impedance and admittance control [7]. Tasks such as peg insertion, connector mating, and surface following additionally require compliance that adapts throughout execution [8], [9]. During search and alignment, the robot should remain compliant, while after contact, stiffness may need to increase along constrained directions and damping should suppress impacts and oscillations.

The ROS control framework has streamlined robot-agnostic access to hardware and simulation through common state and command interfaces [10], [11]. Its standard controllers primarily address position, velocity, effort, and trajectory execution, whereas compliant manipulation requires richer commands that include motion references, stiffness and damping, feedforward terms, nullspace targets, and, for task-space control, task-frame information. Existing compliant-control

packages provide useful functionality, but their command semantics and robot-model access remain inconsistent and are often tied to particular robots, dynamics libraries, or vendor APIs.

This paper addresses this gap with the framework illustrated in Fig. 1. It combines interchangeable control-law plugins with a reusable compliant-control wrapper and robot-model layer, and exposes motion and compliance through standardized joint and Cartesian command interfaces. The Cartesian interface further supports task-aligned compliance by allowing stiffness and damping to be specified in moving task-dependent frames. The contributions of this paper are threefold:

- (1) *A wrapper-plugin architecture for robot-agnostic compliant control*: reusable ROS control wrappers separate controller deployment from interchangeable control-law implementations, while a URDF-backed dynamics module provides the kinematic and dynamic quantities required by compliant controllers.
- (2) *Interfaces for online, task-dependent compliance*: joint and Cartesian command schemas where motion references and compliance parameters are updated together, including stiffness and damping expressed in arbitrary frames. This supports execution pipelines in which compliant directions follow environmental constraints or task geometry.
- (3) *Reference implementations and development tooling*: joint- and Cartesian-space impedance-control plugins demonstrate the proposed interfaces, while the same plugin abstraction supports manual implementations and block-diagram-based controller development using tools such as Simulink.

The remainder of the paper first positions the framework

against related compliant controller packages in ROS. It then presents the wrapper-plugin architecture, robot-model layer, and command interfaces, followed by the reference impedance controllers and the Simulink-based plugin-generation workflow. The framework is evaluated through deployment across multiple robot models and hardware experiments involving curved-fixture following and connector mating under misalignment.

II. RELATED WORK

The standard ROS control abstractions provide portable access to robot hardware and simulation through common state and command interfaces, URDF-based descriptions, and a shared controller manager. This standardization has encouraged broad adoption and a growing ecosystem in which joint position, velocity, effort, and trajectory controllers can be reused across platforms while robot-specific details remain in the hardware layer. Compliant control, however, requires richer commands and model information, including motion references, stiffness and damping, feedforward wrench or torque terms, nullspace targets, and task-frame information. Existing implementations differ substantially in interface design, robot portability, dynamics dependencies, and support for online compliance adaptation. Table I compares several joint- and Cartesian-space compliant controllers along these dimensions (as per July 2026). Repository names are included for package identification and feature verification.

Cartesian impedance-control systems exhibit different trade-offs between portability, model dependence, and extensibility. Robot-specific implementations, such as Franka-based controllers, can exploit mature vendor dynamics and hardware

R – delegated to the robot’s internal controller, P – separate update through parameter interface, F – fixed or preconfigured compliance frame

Fig. 2. Architecture and command execution flow of the proposed framework. The wrapper loads configuration parameters, initializes the model and compensation modules, and loads the selected implementation library. During each update, the wrapper reads joint states, updates the URDF-backed robot model, retrieves the latest buffered Cartesian or joint command, invokes the selected ROS-independent controller plugin, adds configured compensation, applies filtering, finite-value checks, and torque-rate limits, and writes the resulting effort command. Control-law implementations are interchangeable without wrapper recompilation.

integration but are difficult to transfer unchanged to other robots. Robot-agnostic packages improve portability through common hardware interfaces and independent dynamics libraries, although they differ in model dependencies, simulation support, nullspace handling, and feedforward commands. Online gain updates are often exposed through a non-real-time parameter interface, compliance frames are commonly fixed or selected from a configured set, and the control law is generally part of a fixed implementation rather than a runtime-replaceable plugin. Consequently, task-aligned compliance in a moving frame and controller substitution typically require package-specific modifications.

Systems that provide joint impedance alone or combine joint- and Cartesian-space compliance require separate consideration. Joint impedance deserves separate treatment because its command semantics and model requirements differ from task-space control: it acts directly on joint references and gains, does not require Cartesian frame definitions, and may operate with fewer kinematic quantities, while still benefiting from standardized feedforward, compensation, safety, and plugin interfaces. Franka and KUKA stacks provide tightly integrated joint compliance but remain platform-specific. The `compliant_controllers` package by Applied AI Lab introduces a modular chained spring-damper controller with external torque commands and friction compensation, although their simulation setup requires upstream modifications. The IJS controllers support joint- and task-space compliance with nullspace regulation and online gain updates, but depend on the Franka dynamics interface.

Among the compared systems, CRISP [2] is the closest recent counterpart. It is ROS 2-native and robot-agnostic, and targets learning-based policy and teleoperation pipelines with support for simulation, joint-limit handling, nullspace control, feedforward terms, friction compensation, and safety constraints. Its accompanying Python and Gymnasium interfaces provide an integrated workflow for policy deployment and data collection. Our focus is complementary: we define shared joint and Cartesian command schemas, separation between the wrapper and controller plugin for interchangeable control-law implementations, and compatibility with externally generated controllers. Our proposed interface additionally supports online mapping of stiffness and damping into arbitrary task-

dependent frames.

Existing systems provide important subsets of the required functionality, including robot portability, compliant-control features, online variable impedance, and modular software design. However, the surveyed approaches do not offer these capabilities through the same reusable ROS architecture with standardized joint and Cartesian command interfaces, interchangeable ROS-independent control-law plugins, URDF-backed model access, and moving compliance-frame support. The proposed framework integrates these elements within a common execution layer while preserving flexibility through its plugin-based design.

III. PROPOSED FRAMEWORK

A. Architecture Overview

The framework consists of four software components: a generic ROS controller wrapper, a ROS-independent controller plugin interface, a URDF-backed robot-model library, and a standalone command-message package. The wrapper owns middleware-facing execution, including controller initialization, command buffering, hardware-interface exchange, compensation, and torque validation. It is instantiated as Cartesian and joint controller wrappers that share the same execution structure but receive different command types and request different model quantities. The Cartesian wrapper receives task-space commands and manages Cartesian model quantities, whereas the joint wrapper receives joint-space references and gains; their command interfaces are detailed in Section III-C. Both wrappers load an implementation conforming to the same abstract class, whose sole responsibility is to map structured commands and robot state to joint torques without depending on ROS. A separate robot-model library parses the URDF and provides Pinocchio-based kinematic and dynamic quantities [12]. Finally, the message package defines the standardized Cartesian and joint command schemas used by external ROS nodes.

B. Controller Initialization, Lifecycle Management, and Real-Time Execution

Before real-time control begins, each wrapper resolves the robot, joint, and frame parameters, initializes the compensation

TABLE II
OVERVIEW OF THE FIELDS IN THE COMMAND INTERFACES.

Field group	Cartesian command	Joint command
Motion ref.	pose, twist, acceleration	position, velocity, acceleration
Compliance	translational/rotational stiffness and damping matrices	joint stiffness and damping gains
Feedforward	additional end-effector wrench and joint torque	additional joint torque
Redundancy	nullspace target and gains	–
Metadata	joint count, mode	joint count, mode

modules and URDF-backed robot model, and loads the selected controller implementation. Alternative control laws can be deployed by selecting a different implementation library through reconfiguration. Parameters are exposed through standard ROS parameter services and applied during controller initialization. Model construction, memory allocation, and plugin loading therefore remain outside the real-time update path.

When the controller is started, the current robot state is used to initialize the first Cartesian pose or joint target. The wrapper starts torque control only if the selected implementation produces a finite and valid initial output.

Each real-time update follows the sequence shown in Fig. 2: the wrapper reads joint position, velocity, and effort; updates the required robot-model quantities; retrieves the latest command from the real-time buffer; invokes the plugin's control-law step; adds configured gravity, friction, or end-effector-load compensation; applies command filtering, finite-value checks, and torque-rate limits; and writes the final effort command. Optional diagnostics are recorded asynchronously. When the controller is stopped or encounters an error, normal command updates cease. On restart, the command reference is updated from the measured robot state to avoid discontinuities.

C. Standardized Command Interfaces

The command definitions are provided in a standalone package. Table II summarizes their field groups. The Cartesian message carries task-space references, translational and rotational compliance, feedforward terms, and optional nullspace regulation. The joint message provides the corresponding joint-space references, gains, and feedforward torque. Both are accepted from arbitrary ROS nodes and stored in real-time buffers, allowing external command sources to share the same robot-independent command path.

Because stiffness and damping are updated through the reference-command interface, an external application can vary impedance online (i.e., by sending new gain values during controller execution, e.g., across task phases), without modifying the controller.

IV. REFERENCE CONTROLLER IMPLEMENTATIONS

The framework includes reference joint- and Cartesian-space impedance-control plugins that demonstrate how different control laws can be implemented behind the same ROS-independent plugin interface. Both implementations receive structured commands and robot-state information from their

Fig. 3. Illustration of task-aligned compliance during surface following. The robot end-effector tracks a desired trajectory (blue) while maintaining low stiffness along the normal and binormal directions ($\mathbf{n}$, $\mathbf{b}$) and higher stiffness tangentially ($\mathbf{t}$). The behavior is realized by mapping diagonal stiffness and damping matrices through a moving compliance frame attached to the trajectory or surface.

respective wrappers and return joint-torque commands without duplicating ROS integration, model updates, compensation, filtering, or hardware-interface logic.

A. Joint Impedance Controller Plugin

Following the classical impedance-control formulation [13], the joint-space controller renders a virtual spring-damper behavior about the commanded joint state. For desired joint position $\mathbf{q}_d$, velocity $\dot{\mathbf{q}}_d$, stiffness $\mathbf{K}_q$, damping $\mathbf{D}_q$, and optional joint feedforward torques $\boldsymbol{\tau}_{ff}$, it computes

$$\boldsymbol{\tau}_{ji} = \mathbf{K}_q(\mathbf{q}_d - \mathbf{q}) + \mathbf{D}_q(\dot{\mathbf{q}}_d - \dot{\mathbf{q}}) + \boldsymbol{\tau}_{ff}. \quad (1)$$

B. Cartesian Impedance Controller Plugin with Task-Aligned Compliance

The controller is implemented as a Cartesian impedance controller following the formulation by Albu-Schäffer et. al [14]. Let $\mathbf{q}, \dot{\mathbf{q}} \in \mathbb{R}^n$ denote the joint position and velocity, $\mathbf{J}(\mathbf{q}) \in \mathbb{R}^{6 \times n}$ the geometric Jacobian, and $\mathbf{x} = (\mathbf{p}, \mathbf{R}) \in SE(3)$ the end-effector pose, with twists and wrenches expressed in the base frame. The Cartesian pose and velocity errors are

$$\mathbf{e} = \begin{bmatrix} \mathbf{p} - \mathbf{p}_d \\ -\mathbf{R}\boldsymbol{\phi} \end{bmatrix}, \quad \mathbf{e}_v = \mathbf{J}\dot{\mathbf{q}} - \mathbf{v}_d, \quad (2)$$

where $\boldsymbol{\phi} = 2 \log_q(\boldsymbol{\eta}^{-1} \otimes \boldsymbol{\eta}_d)$. Here $\boldsymbol{\eta}$ and $\boldsymbol{\eta}_d$ denote the current and desired end-effector unit quaternions, respectively, and $\log_q$ denotes the quaternion logarithm.

The command interface represents Cartesian stiffness and damping using uncoupled translational ($\mathbf{K}_{pos}, \mathbf{D}_{pos}$) and rotational blocks ($\mathbf{K}_{ori}, \mathbf{D}_{ori}$):

$$\mathbf{K} = \begin{bmatrix} \mathbf{K}_{pos} & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{ori} \end{bmatrix}, \quad \mathbf{D} = \begin{bmatrix} \mathbf{D}_{pos} & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_{ori} \end{bmatrix}. \quad (3)$$

The commanded joint torques generated by the Cartesian plugin are

$$\boldsymbol{\tau}_{cart} = \mathbf{J}^\top (-\mathbf{K}\mathbf{e} - \mathbf{D}\mathbf{e}_v + \mathbf{w}_{ff}) + \boldsymbol{\tau}_{ns}, \quad (4)$$

where $\mathbf{K}$ and $\mathbf{D}$ are Cartesian stiffness and damping matrices and $\mathbf{w}_{ff}$ is an optional command-level feedforward wrench in the base frame. The nullspace term is computed as

$$\boldsymbol{\tau}_{ns} = \mathbf{N}^\top (\mathbf{K}_{ns}(\mathbf{q}_{ns,d} - \mathbf{q}) - \mathbf{D}_{ns}\dot{\mathbf{q}}), \quad (5)$$

where $\mathbf{N}^\top = \mathbf{I} - \mathbf{J}^\top \mathbf{J}^{+ \top}$. The reference implementation uses a damped least-squares Euclidean pseudoinverse for $\mathbf{J}^+$.

C. Task-dependent Compliance Formulation

Tasks such as surface following, insertion, and manipulation along curved paths benefit from the principal compliance directions following the local task geometry, as illustrated in Fig. 3. The external task source constructs an application-specific frame and supplies its orientation with the Cartesian command. For a spatial path, this may be a Frenet–Serret frame (FSF) composed of the local tangent, normal, and binormal vectors [15]; for motion constrained to a surface, it may instead be a Darboux frame formed from the path tangent, surface normal, and their cross product [16]. Following the task-frame mapping approach of Nemec et al. [17], the Cartesian plugin transforms the commanded translational and rotational stiffness blocks as:

$$\begin{aligned} \mathbf{K}_{\text{pos}} &= \mathbf{R}_{\text{task}} \mathbf{K}_{\text{pos,diag}} \mathbf{R}_{\text{task}}^\top, \\ \mathbf{K}_{\text{ori}} &= \mathbf{R}_{\text{task}} \mathbf{K}_{\text{ori,diag}} \mathbf{R}_{\text{task}}^\top, \end{aligned} \quad (6)$$

with analogous mappings for the damping matrices. Their diagonal entries may, for example, be selected as ($d_i = 2\sqrt{k_i}$), corresponding to nominal critical damping. $\mathbf{R}_{\text{task}}$ contains the commanded compliance-frame axes expressed in the base frame. At every control cycle, the plugin applies this mapping using the latest valid frame received through the real-time command buffer; frame construction remains responsibility of the external task source. This separation produces task-aligned compliance along arbitrary translational and rotational principal directions without embedding path- or surface-specific geometry logic in the wrapper or controller plugin.

D. Compensation, Joint Limit Handling, and Filtering

By default, gravity, friction, and end-effector-load compensation are decoupled from the control law and handled directly by the wrapper. Friction compensation uses experimentally identified robot dynamics and friction parameters following the procedure described by Gaz et al. [18].

Both the Cartesian and joint-space wrappers construct the hardware command by combining the output of the controller implementation plugin with the enabled compensation terms:

$$\boldsymbol{\tau}_{\text{cmd}} = \boldsymbol{\tau}_{\text{impl}} + \boldsymbol{\tau}_g + \boldsymbol{\tau}_{\text{fr}} + \boldsymbol{\tau}_{\text{load}} + \boldsymbol{\tau}_{\text{lim}}, \quad (7)$$

where $\boldsymbol{\tau}_{\text{impl}}$ denotes the output of either the Cartesian impedance controller $\boldsymbol{\tau}_{\text{cic}}$ or the joint impedance controller $\boldsymbol{\tau}_{\text{ji}}$, while $\boldsymbol{\tau}_g$, $\boldsymbol{\tau}_{\text{fr}}$, and $\boldsymbol{\tau}_{\text{load}}$ represent gravity, friction, and end-effector load compensation, respectively. This separation ensures that the reusable controller implementation remains independent of robot-specific compensation strategies. Each compensation term can be enabled or disabled through configuration parameters. In addition, the model interface exposes dynamic quantities to the controller implementation plugins, thereby supporting control laws, such as operational-space controllers, that incorporate the full robot dynamics directly rather than treating the corresponding terms as decoupled compensation components [19].

To reduce the risk of reaching mechanical joint limits, the wrapper optionally applies a soft joint-limit torque $\boldsymbol{\tau}_{\text{lim}}$ within a configurable safety margin $\epsilon_i > 0$ of each

joint limit. This follows common torque-level joint-limit avoidance approaches based on repulsive joint-limit potentials or unilateral virtual spring terms [20]. The additional torque is generated independently of the selected controller plugin and becomes active only when the joint approaches its lower or upper position limit:

$$\tau_{\text{lim},i} = \begin{cases} k_{\text{lim},i}(q_{i,\text{min}} + \epsilon_i - q_i) - d_{\text{lim},i}\dot{q}_i, & q_i < q_{i,\text{min}} + \epsilon_i, \\ -k_{\text{lim},i}(q_i - q_{i,\text{max}} + \epsilon_i) - d_{\text{lim},i}\dot{q}_i, & q_i > q_{i,\text{max}} - \epsilon_i, \\ 0, & \text{otherwise} \end{cases} \quad (8)$$

where $k_{\text{lim},i}$, $d_{\text{lim},i}$ define the virtual spring behavior, q_{min} , q_{max} define joint limits and ϵ the corresponding safety margins. The resulting safety contribution is added after the controller plugin output and before final torque validation and rate limiting. This approach uses the same protection mechanism for both joint-space and Cartesian-space controllers without requiring any changes to their underlying control laws. Because the joint-limit term operates directly in joint space, it can influence task tracking as the robot approaches a joint limit. Its effect is bounded by configurable limits and serves as an additional software-level safeguard rather than a replacement for hardware-level joint-limit enforcement.

Before being written to the hardware, the commanded torque is first smoothed using a first-order low-pass filter,

$$\tilde{\boldsymbol{\tau}}_k = \alpha \boldsymbol{\tau}_{\text{cmd}} + (1 - \alpha) \tilde{\boldsymbol{\tau}}_{k-1}. \quad (9)$$

The filtered torque is then rate-limited element-wise to limit the maximum change in commanded torque between consecutive control cycles k to $\Delta\boldsymbol{\tau}_{\text{max}}$:

$$\boldsymbol{\tau}_k = \boldsymbol{\tau}_{k-1} + \text{clamp}(\tilde{\boldsymbol{\tau}}_k - \boldsymbol{\tau}_{k-1}, -\Delta\boldsymbol{\tau}_{\text{max}}, \Delta\boldsymbol{\tau}_{\text{max}}). \quad (10)$$

V. SIMULINK-TO-PLUGIN PIPELINE

Developing and validating low-level robot controllers directly within a ROS package can require substantial middleware-specific code, even when the control law itself is compact. This creates an additional barrier for researchers using block-diagram modeling, automatic code generation, or model-based development tools.

The wrapper–plugin separation introduced in this work provides a natural interface for model-based controller development. As illustrated in Fig. 4, the pipeline supports model-based controller design by converting a structured control model into a loadable plugin for the generic ROS wrapper. The Simulink model uses structured command and state buses as inputs and a torque-command bus as output. These buses match the wrapper’s internal data representation, allowing generated and handwritten controllers to share the same command, state, and output semantics without introducing ROS dependencies into the control model. The pipeline scaffolds the required interface before the control law is authored. It first registers the input and output buses and then generates a template model with the required connections. The user implements only the control law within this template, after which the build process compiles the model into a shared plugin library conforming to the wrapper interface described in Sec. III-A.

Fig. 4. Model-based controller-generation workflow. Automatically generated bus structures expose robot state and control commands to a Simulink model. The authored control logic is compiled as a loadable plugin conforming to the same interface as handwritten C++ implementations.

This separation also enables host-side validation before robot deployment: synthetic command and state inputs can be passed through the generated controller, and the resulting torque output can be inspected or compared against expected behavior.

Unlike robot-specific Simulink toolboxes tied to vendor APIs, the proposed pipeline is robot-agnostic and integrates with the ROS control ecosystem through the wrapper layer. The same generated plugin can execute on different robots or simulators as long as the hardware exposes compatible ROS control interfaces and the configuration provides the appropriate robot description, joints, and frames.

VI. EXPERIMENTAL EVALUATION

The evaluation provides representative system-level show-cases of cross-platform portability and contact-oriented task execution. Portability is checked by deploying the same controller interface across multiple robot models, while hardware performance on the Franka FR3 is examined through curved-fixture following with task-aligned compliance implemented by a moving compliance frame and quick-connector mating under misalignment.

The framework was tested on ROS 2 Humble. All evaluations use the Cartesian wrapper with the Cartesian impedance plugin described in Sec. IV-B. The real-robot experiments were conducted on a Franka FR3, with torque commands exchanged through the Franka Control Interface (FCI) at 1 kHz. For the task experiments, commands were generated with RobotBlockset Python [21], whose motion primitives stream Cartesian pose and twist references, positional and orientational stiffness computed as outlined in Sec. IV-C, feedforward wrench, and task-frame orientation through the proposed command interface (cf. Table II).

A. Reference Implementation Timing

Real-time feasibility was verified with a standalone benchmark on the reference Cartesian impedance plugin (Intel Core i7-14700, 10,000 iterations, FR3 model). One controller update required a mean of $3.82 \mu\text{s}$ (SD $0.34 \mu\text{s}$, max $21.83 \mu\text{s}$), and the update together with wrapper overhead, comprising model update and pose extraction, required a mean of $4.49 \mu\text{s}$ (SD $0.39 \mu\text{s}$, max $22.97 \mu\text{s}$), well below the 1 ms period of the 1 kHz control loop.

B. Cross-Platform Deployment Check

Configuration portability was evaluated by deploying the same Cartesian impedance plugin on a physical Franka FR3 and in simulation using models of the FR3, KUKA LBR iiwa14, Flexiv Rizon 4s, and Universal Robots UR5e. Each robot instance was commanded through the same Cartesian command interface to reach a common task-space target, as shown in Fig. 5. The FR3, LBR iiwa14, and Rizon 4s are seven-degree-of-freedom manipulators, whereas the UR5e has six degrees of freedom. Deployment across both kinematically non-redundant and redundant manipulators demonstrates that the interface is not tied to a particular joint count.

The controller implementation and command schema remained unchanged across all configurations. The only robot-specific adjustments were to the URDF description, joint and frame names, launch configuration, and hardware-interface parameters. Companion launch files and Docker configurations are provided to support reproducible deployment in simulation and on the physical FR3.

C. Curved Surface Following

The second experiment evaluates partially constrained motion along a curved fixture, representative of contact-rich processes such as grinding, polishing, adhesive dispensing, sealing, and deburring. These tasks require tangential progression along a path while maintaining compliant contact in the surface-normal direction. The proposed task-frame mapping rotates the stiff and compliant axes with the local fixture geometry instead of keeping them fixed in the robot base frame.

The experiment uses a 3D-printed, approximately D-shaped fixture with a maximum lateral deviation of 30 mm over a path length of 180 mm. The robot approaches the fixture with a small offset, establishes contact, and progresses along

Fig. 5. Cross-platform deployment of the same Cartesian impedance plugin on simulated Franka FR3, KUKA LBR iiwa14, Flexiv Rizon 4s, and UR5e configurations. The set includes both six- and seven-degree-of-freedom manipulators; robot-specific changes are confined to descriptions, joint and frame definitions, launch files, and hardware-interface parameters.

Fig. 6. Two curved-fixture runs showing contact establishment and progression along different parts of the geometry. The compliant direction is aligned with the local constraint without geometry-specific changes to the motion program. The lower row shows the run with the fixture displaced from its nominal pose.

the curved segment. During traversal, the task frame is continuously updated from the local fixture geometry. Low stiffness of 50 N/m is applied along the surface normal, while higher stiffness of 1000 N/m is retained in the tangential directions.

Fig. 6 shows two representative runs along different parts of the fixture. The same motion command and controller configuration were used in both cases. The end-effector adapted to the changing constraint geometry through the task-frame mapping, without geometry-specific modifications to the motion program.

The task-aligned configuration was compared with a fixed-frame Cartesian-stiffness baseline using representative single-run data over the logged traversal windows. Tracking error was evaluated relative to the commanded reference path and decomposed into components perpendicular and parallel to the local tangent. Task-aligned compliance reduced the lateral RMS error from 16.3 mm to 7.4 mm and the maximum lateral deviation from 40.4 mm to 13.7 mm. Tangential RMS error decreased from 101.7 mm to 18.8 mm, yielding a reduction in total positional RMSE from 103.0 mm to 20.2 mm. The maximum point-to-reference distance also decreased from 24.9 mm to 13.1 mm.

The mean contact-force magnitude was 5.22 N for the fixed-frame case and 5.07 N for the task-frame case, while the corresponding standard deviations were 1.49 N and 1.30 N. With fixed Cartesian gains, the compliant direction becomes progressively misaligned with the surface normal as the path bends, producing increased lateral deviation and substantial drift along the path. Updating the commanded frame orientation with the local geometry preserves the intended normal compliance and limits unwanted tangential interaction.

To evaluate robustness to geometric uncertainty, the fixture was intentionally displaced from its nominal pose in a separate run, shown in the lower row of Fig. 6, while the controller parameters were kept unchanged. Despite this mismatch, the end-effector established and maintained contact throughout the traversal. The low stiffness along the local surface-normal direction accommodated the positional offset, while the higher tangential stiffness preserved progression along the commanded path. These results show that task-aligned compliance improves curved-surface tracking and

Fig. 7. Quick-connector mating under angular misalignment. The first four frames show the proposed task-aligned strategy progressing through approach, contact, self-alignment, and insertion. The final frame shows a representative failure, where binding triggers the axial-force threshold before full seating.

tolerates moderate fixture-placement errors without requiring the motion reference to be retaught or explicitly corrected.

D. Quick-Connector Mating

This experiment evaluates contact-rich mating under angular misalignment using a PVC garden hose quick-connector. The tight mechanical fit and substantial friction make the task highly sensitive to approach errors; misalignment can cause binding, elevated contact wrenches, or failure to fully seat the connector. We evaluate whether online task-aligned compliance can exploit these physical constraints to self-correct alignment during insertion.

In the baseline condition, Cartesian compliance was defined statically in the tool center point (TCP) frame. Stiffness was set high along the TCP z -axis (1000 N/m) to maintain the insertion direction, while lateral translational (50 N/m) stiffness was reduced to permit geometry-constraints-induced correction. In the proposed task-aligned condition, the compliance frame was initialized in the TCP frame but updated online to the FSF (cf. Sec. IV-C), dynamically aligning the compliant directions with the connector geometry. Consequently, the robot advanced along the FSF z -axis while retaining compliance in the degrees of freedom required to compensate for misalignment.

A trial was deemed successful if the connector was fully seated without manual intervention. Under the proposed method, insertion succeeded across all tested angular offsets from 1° to 6° in 1° increments. Conversely, the baseline TCP-frame compliance failed for offsets exceeding 3° , as binding caused the axial-force threshold to be reached prior to full seating.

These results demonstrate that expressing compliance in a task-aligned frame improves robustness to approach pose errors. Without modifying the controller, the proposed formulation doubled the maximum admissible angular misalignment compared to the fixed Cartesian stiffness baseline. The compliant directions allowed contact forces to induce corrective translational and rotational motion, enabling the connector to self-center during insertion rather than bind against the mating surface. Unlike passive mechanisms (e.g., Remote Center of Compliance), our approach dynamically adapts compliance to arbitrary task frames, enabling seamless integration with learning-based manipulation pipelines.

VII. CONCLUSIONS

This work presents a modular, robot-agnostic framework for compliant control that enables the principal compliance

directions to be reoriented online according to local task geometry, which is particularly important for contact-rich manipulation where constrained and compliant directions may vary continuously during task execution.

The framework builds on hardware abstractions in ROS 2 while addressing a common limitation of compliant-control implementations: their reliance on platform-specific dynamics interfaces, which often ties them to particular software stacks and model representations. The framework further separates the control-law implementation from ROS integration and the supporting controller infrastructure through a wrapper-plugin architecture. This separation supports rapid prototyping by allowing control laws to be developed and evaluated without repeatedly implementing the surrounding deployment infrastructure. It is exemplified by block-diagram-based controller development using tools such as Simulink, through which controllers can be developed, validated, compiled, and deployed through the same interface as handwritten C++ implementations. Standardized joint and Cartesian command interfaces allow high-level applications to provide compliance parameters alongside motion references. These parameters can be updated online at arbitrary rates and specified in arbitrary frames, supporting execution pipelines in which the task frame follows environmental constraints or other task-dependent geometry.

The experiments demonstrated the utility of the framework for both cross-platform deployment and contact-rich manipulation. The same controller implementation was deployed across manipulators with different joint counts and kinematic structures, while online updates of the compliance frame supported curved-fixture following and connector mating under misalignment. Beyond the showcased experiments, the framework targets applications in which motion and compliance must be adapted online by high-level command sources. These include teleoperation and shared-autonomy systems, and learned policies that generate motion and interaction parameters during execution.

CODE AVAILABILITY

The proposed framework is publicly available from the authors' GitHub repository under the terms of Apache-2.0 license. The main controller package is available in `smihael/compliant_controllers`. Robot-model support is provided by `smihael/ros2_control_robot_dynamics`, and the command-message definitions by `smihael/compliant_controllers_msgs`. The Simulink generation tools are available in `smihael/compliant_controllers_simulink_pipeline`, while launch files, robot examples, and Docker configurations are provided in `smihael/compliant_controllers_demos`.
