ABSTRACT

Accurate analysis of histopathological images is critical for disease diagnosis and treatment planning. Whole-slide images (WSIs), which digitize tissue specimens at gigapixel resolution, are fundamental to this process but require aggregating thousands of patches for slide-level predictions. Multiple Instance Learning (MIL) tackles this challenge with a two-stage paradigm, decoupling tile-level embedding and slide-level prediction. However, most existing methods implicitly embed patch representations in homogeneous Euclidean spaces, overlooking the hierarchical organization and regional heterogeneity of pathological tissues. This limits current models' ability to capture global tissue architecture and fine-grained cellular morphology. To address this limitation, we introduce a hybrid hyperbolic-Euclidean representation that embeds WSI features in dual geometric spaces, enabling complementary modeling of hierarchical tissue structures and local morphological details. Building on this formulation, we develop BatMIL, a WSI classification framework that leverages both geometric spaces. To model long-range dependencies among thousands of patches, we employ a structured state space sequence model (S4) backbone that encodes patch sequences with linear computational complexity. Furthermore, to account for regional heterogeneity, we introduce a chunk-level mixture-of-experts (MoE) module that groups patches into regions and dynamically routes them to specialized subnetworks, improving representational capacity while reducing redundant computation. Extensive experiments on seven WSI datasets spanning six cancer types demonstrate that BatMIL consistently outperforms state-of-the-art MIL approaches in slide-level classification tasks. These results indicate that geometry-aware representation learning offers a promising direction for next-generation computational pathology.

Keywords Computational pathology · whole-slide images · multiple instance learning · hybrid geometric embedding

1 INTRODUCTION

Histopathological examination is the gold standard for disease diagnosis, forming the foundation for accurate cancer diagnosis and treatment planning [1]. Whole-slide images (WSIs) are central to computational pathology, yet present a critical challenge due to their gigapixel resolution (e.g., $30,000 \times 50,000$ pixels) poses significant computational challenges. To tackle this gigapixel challenge, Multiple Instance Learning (MIL) [2] an emerging dominant solution by decoupling the encoding and decoding processes. It partitions WSIs into small regions (e.g., 224×224 pixels), generating patch embeddings via foundation models (e.g., UNI [3], Virchow2 [4]), and aggregates them via slide-level models (e.g., ABMIL [5], TransMIL [6]). Although practical, previous MIL methods primarily focus on the resolution issue, leaving the intrinsic biological properties of WSIs insufficiently addressed. Specifically, they suffer from three following key limitations:

Geometric trade-offs in modeling multi-level tissue hierarchies. Beyond spatial dependencies and heterogeneity, pathological tissues inherently exhibit a multi-level hierarchical architecture (e.g., cells $\rightarrow$ glands $\rightarrow$ tissues). Most traditional MIL methods rely on Euclidean distance, which excels at capturing locally continuous morphological features but mathematically strug-

Figure 1: WSI geometric representations. (a) Euclidean distance fails to model hierarchical relationships. (b) Hyperbolic geometry naturally encodes the hierarchical structure of pathology.

gles to embed exponential hierarchical growth. Consequently, Euclidean-based activation maps often scatter attention across diagnostic-irrelevant background or stromal regions (Fig. 1 (a)).

To address this, recent pioneering works [7] have introduced hyperbolic geometry to WSI analysis, exploiting its inherent capacity to embed hierarchical topologies. However, pure hyperbolic representations face a fundamental geometric trade-off: their inherent negative curvature distorts fine-grained local morphological details that are naturally better preserved in flat Euclidean spaces. Therefore, a hybrid geometry is required to harmonize these spaces, precisely concentrating heatmap activations on tumor boundaries while suppressing irrelevant background noise (Fig. 1 (b)).

Inadequate modeling of long-range 2D spatial dependencies. Effectively capturing global tissue structures requires modeling inter-tile relationships across thousands of patches, which State Space Models (SSMs) excel at (Fig. 2 (a)). Among them, the Structured State Space Sequence (S4) model [8] is an early and representative formulation that offers stable long-context modeling through structured state-space parameterization. Later selective SSMs such as Mamba further improve sequence modeling efficiency and adaptivity, but their selective scanning mechanism still imposes an ordered 1D traversal over spatial tokens, which can introduce directional bias and structurally conflicts with the non-directional 2D grid topology of WSIs (Fig. 2 (c)). In contrast, S4 provides a more suitable basis for our setting: its structured global recurrence can model long-range interactions without relying on rigid scan directions, thereby better aligning with the complex 2D spatial organization of pathological tissues while maintaining linear complexity and stable global receptive fields (Fig. 2 (b)).

Vulnerability to pronounced regional heterogeneity. A single WSI is a highly heterogeneous microenvironment composed of morphologically distinct regions, such as dense tumor areas, necrotic zones, and normal stroma. Traditional MIL methods attempt to fit these divergent distributions using a single unified network backbone. This often leads to parameter dilution and task interference, resulting in strong performance in dominant regions but severe bias or underfitting in others [9]. Effectively disentangling these highly varied histological features remains a significant bottleneck, necessitating a dynamic routing mechanism that can adaptively assign specialized computational resources to distinct morphological patterns.

Building upon these insights, we propose **BatMIL** (Fig. 3), a novel MIL framework that conceptually bridges S4, MoE, and geometric representation learning to systematically address the aforementioned limitations. Specifically, we design a cascaded backbone network that utilizes S4 as the core for unbiased 2D global context modeling, while introducing a mixture-of-experts (MoE) module to dynamically route heterogeneous regional features. Furthermore, we develop a hybrid geometric representation module to jointly embed WSI features into a hyperbolic-Euclidean space, fully encapsulating the hierarchical tissue topology without sacrificing local details. Our main contributions are summarized as follows:

- We propose BatMIL, a novel geometry-aware MIL framework that fundamentally addresses the challenges of ultra-long spatial modeling, regional heterogeneity, and hierarchical tissue topologies in WSI analysis.
- We develop a novel cascaded S4-MoE backbone (Fig. 2 (d)). The S4 module acts as an unbiased engine for

capturing global 2D context with linear complexity, while the pioneering integration of the MoE module dynamically routes heterogeneous tissue patches to specialized experts, mitigating feature homogenization.

- We design a hybrid hyperbolic-Euclidean representation module. By harmonizing the hierarchical embedding capacity of hyperbolic geometry with the local morphological sensitivity of Euclidean space, this dual-space approach significantly concentrates diagnostic attention and suppresses irrelevant background noise.
- Experiments on seven WSI datasets spanning diverse cancer types demonstrate that BatMIL outperforms thirteen state-of-the-art MIL methods across multiple downstream tasks, establishing a new paradigm for structured representation in computational pathology.

2 RELATED WORK

2.1 Multiple Instance Learning

Deep learning for WSI analysis has evolved toward a two-stage MIL paradigm, separating tile-level embedding and slide-level modeling. ABMIL [5] addresses it by implementing a gated attention mechanism to adaptively weight informative tiles. Building on this, CLAM [10] imposes instance-clustering constraints to encourage diverse and discriminative feature learning, thereby improving model generalization. Furthermore, DSMIL [11] incorporates contrastive learning by combining instance- and bag-level supervision to better distinguish informative tiles. On the other hand, DTFD-MIL [12] proposes a double-tier feature distillation framework that utilizes pseudo-bags to virtually expand the training set, enhancing robustness in small-sample scenarios.

However, traditional MIL methods often assume instances are independent, failing to capture the spatial and morphological inter-tile relationships. To address this, graph-based and multi-scale hierarchical methods were introduced. Patch-GCN [13] hierarchically aggregates instance-level histology features via a Graph Convolutional Network (GCN) to model local and global topological structures. Similarly, ZoomMIL [14] builds WSI representations by aggregating tissue-context information from multiple magnifications, while HiGT [15] introduces a hierarchical graph transformer to learn short-range local details and long-range global patterns. Despite successfully capturing spatial contexts, these methods rely heavily on explicitly defined graph topologies or rigid scales, limiting their flexibility.

To model global patch correlations without manual topological priors, Transformer-based methods have been widely adopted. TransMIL [6] overcomes the instance independence challenge by introducing a Transformer-based architecture, utilizing the Nyström approximation of the self-attention mechanism to explicitly model these correlations with pseudo-linear complexity. However, for the extreme sequence lengths inherent in gigapixel WSIs, such approximations still face memory bottlenecks and degradation in capturing fine-grained long-range dependencies. To explicitly improve long-context understanding, GigaPath [16] adopts a cascaded structure and leverages the LongNet architecture. While its dilated attention effectively scales to extreme sequence lengths, the massive parameter count

Figure 2: Comparison of SSM structures. (a) SSM (State Space Model), (b) S4 (Structured State Space Sequence Model), (c) Mamba (Selective State Space Model), (d) S4-MoE (Ours).

of GigaPath imposes a severe computational hardware burden compared to lightweight aggregators.

Recently, State Space Models (SSMs) have emerged as a promising paradigm to break the computational bottlenecks of attention mechanisms while maintaining effective global receptive fields. Leveraging true linear complexity, S4MIL [17] introduces the structured state space sequence (S4) model to WSI analysis, providing robust long-range dependency modeling. Subsequent works, such as MambaMIL [18] and MamMIL [19], adapt the Mamba architecture to capture inter-tile dependencies efficiently through selective scanning mechanisms, while PathRWKV [20] explores linear recurrent neural networks for scalable WSI modeling.

However, all of these previous methods solely embedded their feature representations in Euclidean space. This geometric constraint prevents them from explicitly capturing the intrinsic tree-like hierarchical topology of pathological structures. Furthermore, these unified network architectures lack the specialized capacity to dynamically adapt to the pronounced regional heterogeneity present in WSIs.

2.2 Mixture of Experts in Transformers

Mixture of Experts (MoE) provides an elegant paradigm for efficient model scaling by decoupling computational cost from total parameter count [21]. In Transformer architectures, this is achieved by replacing standard dense Feed-Forward Networks (FFNs) with a sparse ensemble of parallel "expert" subnetworks. For each input token, a lightweight gating network (router) dynamically activates only a sparse subset of these experts. Following its initial integration into Transformers via GShard [22], subsequent architectures like the Switch Transformer [23] streamlined the paradigm using a top-1 routing mechanism, coupled with auxiliary load-balancing losses to mitigate expert collapse. More recently, models such as Mixtral 8x7B [24] have demonstrated the robust scalability of top-k routing, achieving state-of-the-art performance. Beyond natural language processing, Vision MoE (V-MoE) [25] extended this architecture to computer vision by routing individual image patches. In the context of computational pathology, this dynamic patch-level routing offers a highly promising solution to

the pronounced regional heterogeneity of WSIs, allowing morphologically distinct tissue patches to be adaptively processed by specialized experts rather than a constrained unified backbone.

2.3 Hyperbolic Space

Recent advances in WSI analysis have increasingly recognized the geometric limitations of traditional Euclidean spaces, prompting the exploration of hyperbolic neural networks. To better capture the intrinsic hierarchical organization of tissue structures, methods such as HyperPath [7] and HVHM [26] have embedded WSI features into hyperbolic spaces. By exploiting the exponential volume growth inherent to hyperbolic geometry, these approaches explicitly model tree-like tissue hierarchies with significantly lower distortion than early Euclidean-based MIL methods. However, these pure hyperbolic representations face a fundamental geometric trade-off [27, 28]. While hyperbolic space excels at capturing global topological hierarchies, its inherent curvature often distorts fine-grained local and discriminative morphological features—attributes that are naturally better preserved in flat Euclidean spaces. Consequently, effectively harmonizing these two geometries to jointly model global hierarchical structures while preserving local feature discriminability remains a critical open challenge, directly motivating the hybrid geometric representation proposed in our work.

3 METHODS

3.1 WSI Pre-processing and Embedding

To enable effective feature extraction and subsequent slide-level analysis on WSIs, we adopted a systematic preprocessing pipeline to filter uninformative regions and generate high-quality tiles. For a given WSI, we first load it at 0.5 microns-per-pixel (mpp) resolution. To avoid redundant computation on the background, we compute the luminance of the slide and apply Otsu's thresholding to generate a binary foreground mask. The slide is then cropped into bounding boxes encompassing the tissue regions.

As shown in Fig. 3(a), these bounding boxes are split into a grid of non-overlapping tiles, each with a size of 224×224 . The

Figure 3: Overview of BatMIL. (a) A WSI is first partitioned into tiles, then encoded into embeddings with a pathological foundation model. (b) S4-MoE employs WSI-specialized experts to extract domain-specific features. (c) The HDE module maps features from Euclidean space into a hyperbolic manifold to capture hierarchical relationships. (d) The GHS module integrates embeddings from both hyperbolic and Euclidean geometries to generate a multi-scale representation.

WSI can then be represented as a set of tiles $\{P_{i,j}\}$. To ensure these samples are useful for pathological analysis, we adopt a rigorous screening process to exclude low-quality samples. First, we discard any tile where the tissue occupancy is below 10%. Second, we eliminate tiles with insufficient pixel variation by computing the standard deviation across the RGB channels; tiles with an average standard deviation of less than 5 on a 0–255 scale are removed. Additionally, we filter out anomalous tiles containing excessive pure background, specifically discarding those where more than 50% of the pixels have zero intensity.

The remaining tiles contain meaningful pathological information, and we subsequently utilize the tile-level encoder from GigaPath [16] to convert them into compact semantic feature vectors. This feature extraction step improves both the training efficiency of the downstream slide-level backbone and its overall performance in WSI-level analysis.

3.2 Structured State Space Sequence Module

To effectively capture global tissue structures without the quadratic computational bottleneck of standard Transformers or the 1D spatial bias of Mamba, we employ the Structured State Space Sequence (S4) model as the core of our cascaded backbone. The S4 module is designed to jointly model global context and local details across tens of thousands of patches with linear complexity.

For an input sequence of patch embeddings x , we first apply layer normalization (LN) to stabilize the distribution. The features are then processed by the S4 transformation, which leverages HiPPO (High-order Polynomial Projection Operators) initialization. This enables the stable retention of long-range memory and inherently aligns with the non-directional 2D spatial topology of WSIs. To facilitate feature reuse and ensure stable gradient flow in deep networks, we introduce an element-wise residual connection via DropPath:

$$x_{S4} = x + \text{DropPath}(S4(\text{LN}(x))) \quad (1)$$

This unbiased processing empowers the S4 branch to construct a robust global receptive field while preserving local morphological details.

3.3 MoE Routing

WSIs are highly heterogeneous microenvironments comprising distinct regions. Traditional unified networks often suffer from parameter dilution when fitting these divergent distributions. To address this pronounced regional heterogeneity, the updated features from the S4 branch are fed into a sparse MoE module. We instantiate $k=4$ expert sub-networks, each formulated as a two-layer feedforward network with GELU activation and dropout to enhance non-linear expressiveness. Instead of routing all patches through the same dense layers, a lightweight gating network dynamically selects the top-2 specialized experts for each individual patch. The gating network computes logits that are normalized via softmax to yield routing weights w_j . The outputs of the selected experts are then aggregated and residually fused:

$$x_{MoE} = x_{S4} + \text{DropPath}\left(\sum_{j \in I} w_j \cdot E_j(\text{LN}(x_{S4}))\right) \quad (2)$$

where I is the set of selected expert indices, w_j is the gating weight, and E_j represents the j -th expert. Through this dynamic sparse activation, computational resources are adaptively assigned to morphologically distinct regions.

Following the cascaded S4-MoE backbone, we apply global max-pooling along the patch sequence dimension to aggregate the patch-level features into a unified slide-level representation, preserving the most discriminative spatial responses:

$$x_{\text{slide}} = \text{MaxPool}(x_{MoE}, \text{dim} = 1) \quad (3)$$

The slide-level feature x_{slide} is then repeated to match the token count required for subsequent multi-task learning, yielding the final output tensor used for task-specific predictions.

3.4 Hybrid Geometric Representation

While the S4-MoE backbone effectively extracts slide-level representations, conventional MIL methods embed these features exclusively in Euclidean space. Euclidean geometry naturally preserves fine-grained local morphological details via the

L_2 norm, but mathematically struggles to model the exponential tree-like hierarchical architecture intrinsic to pathological tissues. To capture this broader hierarchical scale, we introduce hyperbolic geometry via the Poincaré ball model $\mathbb{M}_c^n$, governed by the manifold curvature c . Its distance metric D_{hyp} is derived from Möbius addition ($\oplus_c$):

$$D_{\text{hyp}}(\mathbf{x}, \mathbf{y}) = \frac{2}{\sqrt{c}} \operatorname{arctanh} \left(\sqrt{c} \left\| -\mathbf{x} \oplus_c \mathbf{y} \right\| \right) \quad (4)$$

This manifold embedding scales exponentially with the radius, effectively accommodating hierarchical tissue structures with minimal distortion. However, this global advantage introduces a geometric trade-off: pure hyperbolic space’s inherent negative curvature can distort local discriminative features that are otherwise stable in flat Euclidean spaces.

Recognizing that hyperbolic geometry generalizes Euclidean geometry as the curvature approaches zero ($\lim_{c \rightarrow 0} D_{\text{hyp}}(\mathbf{x}, \mathbf{y}) = 2\|\mathbf{x} - \mathbf{y}\|$), we propose a Geometric Hybrid Strategy (GHS) to harmonize both spaces. While fusion can technically be achieved via simple vector concatenation or complex distance projection mechanisms, we empirically adopt a weighted-addition strategy (Fig. 3d) for its efficiency and stability. For a given slide-level feature h , we generate a Euclidean embedding $z_E \in \mathbb{E}^m$ and a hyperbolic embedding $z_H \in \mathbb{H}_c^m$, where $z_H = \exp_0^c(W_H h)$ utilizes the exponential map to incorporate the manifold curvature c . To bridge the geometric divide, we map the hyperbolic representation back to the tangent space via the logarithmic map ($\log_0^c$) and fuse it with the Euclidean feature:

$$z_{\text{hybrid}} = \alpha \cdot z_E + (1 - \alpha) \cdot \log_0^c(z_H) \quad (5)$$

Here, $\alpha \in \mathbb{R}^m$ is a learnable gating parameter (where m is the embedding dimension) that dynamically balances the two geometries. By maintaining the dimensionality and utilizing the curvature c , this unified representation effectively combines the hierarchical embedding capacity of hyperbolic space with the local morphological sensitivity of Euclidean space.

4 EXPERIMENTS

4.1 Datasets and Downstream Tasks

We validate BatMIL on 6 core downstream tasks across seven WSI datasets, covering diverse diagnostic scenarios in computational pathology (Tab. 1). In the **CAMELYON16** [29] and **CAMELYON17** [30] datasets, the **Breast Metastasis (BrMet)** task evaluates the model’s capability to classify lymph nodes as normal or tumorous. The **PANDA** [31] dataset is used for **ISUP grading (G-Score)** to assess prostate cancer aggressiveness, which requires fine-grained analysis of cellular patterns. Furthermore, the **TCGA** [32] datasets are utilized to evaluate multiple diagnostic objectives. Specifically, the **TCGA-NSCLC** dataset is used to predict **AJCC-defined tumor staging (T-Stage)**, a metric reflecting the tumor’s local progression. The **TCGA-BRCA** dataset evaluates **HER2 (IHC-HER2)** expression status to assess suitability for targeted therapy. For the **Cancer Grading (GRADE)** task, the **TCGA-BLCA** dataset is employed to determine tumor differentiation levels. Finally, the **TCGA-CESC** dataset, associated with the **Lymphovascular Invasion (LymInv)** task, identifies the subtle presence of cancer invasion into lymphatic or vascular channels.

Table 1: Implemented datasets and corresponding downstream tasks.

Dataset	Number of WSIs	Task	Organ
CAMELYON16	400	BrMet	Lymph Node
CAMELYON17	500	BrMet	Lymph Node
PANDA	10616	G-Score	Prostate
TCGA-BLCA	926	GRADE	Bladder
TCGA-BRCA	3121	IHC-HER2	Breast
TCGA-CESC	604	LymInv	Cervix
TCGA-NSCLC	3210	T-Stage	Lung

4.2 Implementation Details

All models were trained for 100 epochs using the AdamW optimizer [33]. The learning rate was modulated by a half-cycle cosine annealing schedule, smoothly decaying to 10% of its initial value by the final epoch. We conducted a hyperparameter search for the initial learning rate across three values (1×10^{-4} , 1×10^{-5} , and 1×10^{-6}), reporting the best performance for each model. During training, we generally employed a batch size of 8 and a maximum sequence length of 4,096 tile features. For the PANDA dataset, these settings were adjusted to a batch size of 64 and a maximum of 512 tile features to accommodate dataset-specific distribution variances. Model performance was evaluated using five-fold cross-validation. We report the average C-index for survival prediction tasks and accuracy, AUROC, and F1-score for classification tasks. All experiments were implemented in Python 3.12.12 using PyTorch 2.9.0 and CUDA 12.8, running on four NVIDIA RTX 4090 GPUs. The foundational preprocessing and training pipeline was supported by UnPuzzle [34].

4.3 Comparison with SOTA Methods

We rigorously evaluate BatMIL against thirteen SOTA methods grouped into four mainstream architectures. Specifically, **ABMIL** [5], **CLAM** [10], **DSMIL** [11], and **DTFD-MIL** [12] are attention-based methods; **PatchGCN** [13], **Zoom-MIL** [14], and **HiGT** [15] are hierarchical methods; **Trans-MIL** [6] and **GigaPath** [16] are Transformer-based methods; and **S4MIL** [17], **MambaMIL** [18], **MamMIL** [19], and **PathRWKV** [20] are SSM-based methods. Performance is measured via 5-fold cross-validation using AUROC, Accuracy, and F1-Score. The quantitative results are presented in Tab. 2.

Attention-based methods. Attention-based methods excel at isolating discriminative local patches but often struggle with global spatial context. On the CAMELYON17 dataset, BatMIL demonstrates superior generalization, exceeding DTFD-MIL by 6.2% in AUROC and outperforming CLAM by 2.0% in Accuracy. For tasks requiring fine-grained grading like PANDA, BatMIL’s AUROC, Accuracy, and F1-Score surpass CLAM by 1.3%, 2.4%, and 2.7%, respectively. This indicates that BatMIL effectively avoids the local feature bias commonly observed in standard attention mechanisms. However, for tasks highly dependent on specific localized biomarker expressions, such as IHC-HER2 (TCGA-BRCA) and LymInv (TCGA-CESC), BatMIL’s AUROC and F1-Score are slightly lower than optimal

Table 2: Performance comparison with thirteen methods. (Note: Standard deviations σ are represented by symbols: $\ddagger$ for $\sigma \leq 0.005$, $\dagger$ for $0.005 < \sigma \leq 0.015$, and $*$ for $\sigma > 0.015$)

methods like DSMIL or DTFD-MIL, though it still maintains the highest Accuracy. This discrepancy suggests that while BatMIL is robust overall, classical attention models remain highly competitive when diagnostic evidence is extremely sparse and localized.

Hierarchical-based methods. Hierarchical methods are designed to explicitly model the multi-scale spatial topology of tissue. Compared to PatchGCN, ZoomMIL, and HiGT, BatMIL consistently establishes new state-of-the-art results across five datasets (CAMELYON16, CAMELYON17, PANDA, TCGA-BLCA, and TCGA-CESC). Most notably, in the challenging BrMet task on CAMELYON17, BatMIL improves upon ZoomMIL by remarkable margins of 19.1% in AUROC, 19.5% in Accuracy, and 19.8% in F1-Score. This demonstrates that BatMIL’s architectural design models multi-level tissue structures and tumor microenvironments far more effectively than existing graph- or tree-based hierarchical paradigms. While performance on TCGA-BRCA and TCGA-NSCLC shows minor fluctuations in F1-Score, BatMIL still secures the highest Accuracy and AUROC.

Transformer-based methods. Transformer-based models, such as TransMIL and GigaPath, are powerful in capturing global contextual representations. On the CAMELYON16 dataset, TransMIL achieves a marginally higher F1-Score than BatMIL. This minor drop can be attributed to the relatively small sample size of CAMELYON16, which may cause slight performance fluctuations in BatMIL. However, on larger or more heterogeneous datasets, BatMIL exhibits significant superiority. For instance, BatMIL outperforms TransMIL by 7.8% in AUROC on CAMELYON17 and significantly exceeds

GigaPath across PANDA and TCGA-BLCA metrics. This demonstrates that BatMIL better balances global dependency tracking with local morphological preservation compared to standard self-attention architectures.

SSM-based methods. SSMs provide an efficient alternative for modeling extremely long sequences in WSIs. As shown in Tab. 2, BatMIL achieves the highest AUROC, Accuracy, and F1-Score among all SSM-based competitors on CAMELYON17, PANDA, and TCGA-BLCA. Notably, BatMIL surpasses the strong PathRWKV baseline by 5.6% in AUROC on CAMELYON17 and 6.0% in F1-Score on TCGA-BLCA. Although S4MIL achieves a higher F1-Score on CAMELYON16 and TCGA-BRCA, BatMIL still dominates in overarching Accuracy. These results highlight that BatMIL more effectively adapts to heterogeneous pathological features and captures long-range dependencies without being heavily impacted by the sequence-length constraints or sample imbalances that challenge current SSM algorithms.

4.4 Efficiency Analysis

Fig. 5 presents the performance and efficiency comparison on the PANDA dataset. The x-axis represents the inference time (s), the y-axis denotes the accuracy on the PANDA dataset, and the bubble size corresponds to the number of model parameters (Params(M)). BatMIL achieves the highest accuracy among all evaluated methods while maintaining a moderate parameter count of 9.76M and reasonable inference speed. Compared to heavier architectures such as GigaPath (86.34M) and ZoomMIL (86.30M), BatMIL delivers superior accuracy with significantly

Figure 4: Grad-CAM visualization for different MIL methods. Traditional Euclidean space-based methods exhibit highly scattered heatmaps, incorrectly attending to large swaths of benign background stroma. Some models manage partial localization but still suffer from prominent false-positive activations or dispersed background noise. Meanwhile, BatMIL accurately identifies the multi-scale spatial relationships among tiles.

lower computational overhead. Conversely, when compared to lightweight models like ABMIL (0.90M), MamMIL (0.99M), CLAM (1.19M), and S4MIL (1.35M), BatMIL yields substantial accuracy improvements with only a marginal increase in inference time. Overall, BatMIL achieves an optimal trade-off between diagnostic accuracy, computational efficiency, and model complexity.

4.5 Visualization Analysis

To assess BatMIL’s ability to localize pathological regions during WSI representation learning, we conduct Grad-CAM [35] visualization on the CAMELYON16 dataset. As shown in Fig. 4, we present two representative cases, each including the raw WSI, ground-truth (GT) metastasis annotation, and attention heatmaps from baseline methods and BatMIL. Red regions in the GT maps indicate metastatic lesions.

Traditional MIL methods encode patches in a single Euclidean feature space, limiting their ability to capture hierarchical tissue topology and local morphological heterogeneity. As a result, their attention are often scattered and redundant. ABMIL and CLAM produce diffuse activations that extend into normal tissue. DSMIL and PatchGCN partially highlight abnormal regions but still introduce non-target responses. DSMIL falsely activates on a benign region in the first case, while PatchGCN shows weak background activations across normal breast tissue, likely due to sensitivity to local intensity variations. These artifacts reduce their spatial alignment with true lesions. In contrast, BatMIL generates more focused and precise heatmaps, accurately highlighting metastatic regions while suppressing activations in adjacent normal tissue. Its attention distribution closely matches the ground-truth annotations, demonstrating stronger localization ability and robustness to heterogeneous pathological backgrounds.

5 DISCUSSION

5.1 Ablations on the Proposed Components

To systematically evaluate the contribution of each architectural innovation, we conducted ablation studies (Tab. 3) alongside Grad-CAM visualization experiments (Fig. 6). Using S4MIL as the baseline, we first analyze the impact of the S4-MoE backbone. Quantitatively, S4-MoE demonstrates superior capability in handling complex pathological tissues, improving the AUROC by 0.053 on TCGA-BLCA and achieving an accuracy of 0.656 on TCGA-NSCLC. These improvements indicate that the MoE module effectively disentangles regional heterogeneity, preventing the parameter dilution often seen in unified networks when processing morphologically divergent tumor microenvironments. This is directly mirrored in the qualitative visualizations: while the baseline S4MIL often disperses attention across large swaths of benign tissue, the dynamic routing in S4-MoE effectively shifts the model’s focus toward pathological abnormalities, successfully filtering out background stroma.

Building upon the S4-MoE backbone, we explicitly ablate the Geometric Hybrid Strategy (GHS) module by comparing the S4-MoE variant against the final BatMIL framework. This comparison isolates the specific contribution of the dual geometric representation. We demonstrate that the choice of geometric fusion strategy within the GHS module profoundly affects both predictive performance and visual precision. We compared three strategies: concatenation (BatMIL_C), projection (BatMIL_P), and weighted-addition (BatMIL). As shown in Tab. 3, both BatMIL_C and BatMIL_P fail to consistently outperform S4-MoE. Specifically, BatMIL_C degrades accuracy on PANDA due to the curse of dimensionality and feature redundancy, while BatMIL_P underperforms on the CAMELYON17 dataset because projecting hyperbolic distances into a flat Euclidean space causes a critical loss of its core exponential characteristics. Visually, these fusion methods fail to elegantly integrate the complementary

Figure 5: Comparison with SOTA methods in inference time and parameters on the PANDA dataset. The scatter plot visualizes the trade-off between diagnostic accuracy (y-axis) and computational efficiency (x-axis), with bubble size representing the total number of model parameters (in millions). BatMIL (top-left) achieves the SOTA accuracy on the PANDA dataset while maintaining a moderate parameter count (9.76M) and competitive inference speed.

geometric priors. The two embedding spaces interfere with one another, resulting in highly redundant and scattered Grad-CAM activations that mistakenly attend to normal tissue regions. In contrast, BatMIL with the weighted-addition strategy consistently achieves the best overall performance across most core metrics. By utilizing a learnable gating parameter to balance the two spaces element-wise, this strategy prevents feature conflict. Visually, this translates to the most precise attention alignment with ground-truth annotations, concentrating heavily on metastatic and malignant regions with near-zero background noise. This confirms that the weighted-addition strategy creates a mathematically harmonious representation, successfully preserving both the global hierarchical embedding capacity of the hyperbolic space and the local morphological sensitivity of the Euclidean space to locate critical diagnostic features.

5.2 Hyperbolic Distance Embedding Analysis

The manifold curvature hyp_c is the defining parameter of the Poincaré ball model, directly controlling its capacity to embed tree-like structures. To study its effect on BatMIL, we evaluated four curvature values: $hyp_c \in \{0.05, 0.075, 0.1, 0.2\}$. As demonstrated in Tab. 4, BatMIL achieves optimal performance across most datasets when $hyp_c = 0.1$. For example, on the CAMELYON16 dataset, the AUROC peaks at 0.996 for $hyp_c = 0.1$, outperforming the configurations of 0.05, 0.075, and 0.2 by margins of 0.020, 0.011, and 0.025, respectively. Similar performance peaks are observed in the PANDA, TCGA-BLCA,

and TCGA-BRCA datasets for this curvature value. This behavior highlights a fundamental geometric trade-off. When hyp_c is too small (e.g., 0.05), the manifold becomes nearly flat, which strips the network of its ability to model the exponential growth of hierarchical tissue structures. Conversely, when hyp_c is too large (e.g., 0.2), the extreme negative curvature heavily distorts local geometric relationships, harming the model’s ability to discriminate fine-grained cellular patterns. The empirical optimum of $hyp_c = 0.1$ strikes the perfect mathematical balance, preserving the macroscopic hierarchical topology while maintaining microscopic morphological fidelity.

5.3 The Interpretability of MoE Routing Mechanisms

To examine whether the MoE router learns meaningful expert selection, we analyze both the standalone performance of each expert and the routing behavior on the CAMELYON16 dataset (Fig. 7). When evaluated independently, the four experts show different levels of discriminative ability, with Expert 3 achieving the best performance, followed by Expert 2, Expert 4, and Expert 1.

This performance hierarchy is reflected in the learned routing probabilities. For each input token, our MoE module activates only the top-2 experts among four candidates. The router assigns the highest probabilities to Expert 3 and Expert 2, with scores of 0.53 and 0.30, respectively. After top-2 selection, their routing weights are renormalized to 0.639 and 0.361, while Expert 1 and Expert 4 are suppressed. This indicates that the

Figure 6: Grad-CAM visualization of ablation studies. S4MIL often disperses attention across benign tissues, while S4-MoE effectively shifts the focus toward pathological abnormalities. BatMIL_c and BatMIL_p exhibit scattered and redundant activations due to geometric feature interference. In contrast, BatMIL achieves the most precise attention alignment with the ground truth, successfully filtering out irrelevant background noise.

router does not select experts arbitrarily; instead, it prioritizes the experts with stronger standalone representational capacity.

More importantly, the top-2 fusion strategy outperforms any individual expert. The fused MoE output achieves an AUROC of 0.989, an accuracy of 0.984, and an F1-score of 0.977, surpassing the best single expert, Expert 3. This suggests that Expert 2 provides complementary information that further improves the representation, whereas weaker experts may introduce noisy or less relevant features. Therefore, the sparse top-2 routing mechanism provides an interpretable and effective balance between single-expert selection and dense expert aggregation, enabling BatMIL to selectively combine the most

Figure 7: Interpretability of the MoE routing mechanism on the CAMELYON16 dataset. The bar chart compares the individual performance of four experts against their fused performance. The router (num-experts=4, top-k=2) adaptively assigns the highest probabilities (0.53 and 0.30) to the two best-performing experts (Expert 3 and Expert 2). After weight renormalization (0.639 and 0.361, respectively), the sparse fusion of these two experts achieves the highest overall performance, demonstrating the advantage of selective expert activation over single-expert or dense routing strategies.

useful pathological representations while avoiding unnecessary computational cost.

5.4 Limitations and Future Work

Despite establishing a robust geometry-aware paradigm, BatMIL exhibits certain limitations. In tasks where diagnostic evidence is extremely sparse and highly localized, such as predicting IHC-HER2 status in the TCGA-BRCA dataset, or identifying subtle Lymphovascular Invasion in TCGA-CESC dataset, BatMIL’s performance is slightly lower than classical attention models like DSMIL. This discrepancy implies that while BatMIL excels at modeling macro-architectural hierarchy and global context, its robust global prior may occasionally over-smooth extremely weak, highly localized cellular signals. Additionally, the current S4-MoE architecture employs a statically defined number of expert sub-networks ($k=4$). Given the varying

complexity across different cancer types, dynamically scaling the number of experts or introducing continuous routing mechanisms could further optimize resource allocation. Finally, while the S4 backbone maintains linear sequence complexity, maintaining dual geometric embeddings and sparse routing slightly increases memory overhead compared to ultra-lightweight aggregators. Addressing these sparse-signal sensitivities and optimizing the memory footprint of the hybrid geometric layer will be the primary focus of our future research toward clinical deployment.

6 CONCLUSION

In this paper, we proposed BatMIL, a novel framework designed to address the limitations of existing MIL methods that embed pathological tissue representations in a single Euclidean space while overlooking hierarchical structure and regional heterogeneity. Specifically, we designed a hybrid hyperbolic-Euclidean geometric representation that jointly embeds WSI features into dual geometric spaces to facilitate hierarchical embedding. Building on this, we designed an S4-MoE module that efficiently encodes long-range dependencies with linear computational complexity, and dynamically adapts to the pronounced regional heterogeneity of pathological tissues through a MoE routing mechanism. Extensive experiments on seven WSI datasets across six cancer types demonstrate that BatMIL consistently outperforms thirteen SOTA MIL methods across six downstream tasks. Comprehensive ablation studies and interpretability analyses further confirm the effectiveness of each component and the rationality of the weighted-addition strategy. In summary, BatMIL establishes a new paradigm for geometry-aware representation learning in computational pathology, and could provide a promising direction for the future development of more accurate and interpretable clinical decision-support systems.
