

REACT: Environment-Adaptive Architecture for Continuous Formation Navigation of Wheeled Mobile Robots

Jianghong Dong¹, Yifeng Zhang², Jiawei Wang³, Mengchi Cai¹, Keqiang Li¹, and Guillaume Sartoretti²

Abstract—Formation control of wheeled mobile robots (WMRs) has been extensively studied due to its broad applications in fields such as logistics transportation, environmental monitoring, and search and rescue. However, most existing works mainly focus on tracking predefined formations, which limits their adaptability to complex real-world environments. To address this, we propose REACT (Real-time Environment-Adaptive architecture for Continuous formation navigation), a hierarchical architecture integrating centralized formation generation and distributed formation maintenance. Specifically, our upper layer generates new environment-adaptive formations when necessary and uses our proposed TCF-R2T (Trajectory-Conflict-Free Robot-to-Target assignment) algorithm to compute conflict-free WMR-to-target assignments in polynomial time, enabling timely formation transitions without trajectory conflicts. At the lower layer, each WMR executes our developed JSTP (Joint Spatio-Temporal trajectory Planning) method to maintain the generated formation by simultaneously optimizing spatial positions and temporal durations, thereby enhancing coordination among WMRs and enabling continuous navigation in obstacle-rich environments and dynamic-obstacle scenarios. Both simulation and real-world experiments validate the effectiveness and practical applicability of REACT. Experimental videos are available on our [project website](#).

Index Terms—Swarm robotics, cooperating robots, wheeled mobile robots, formation control.

I. INTRODUCTION

FORMATION control of multiple wheeled mobile robots (WMRs) has been extensively studied over the past decades due to its broad applications in areas such as collaborative transportation [1], smart warehouses [2], resource exploration [3], and environmental monitoring [4]. The primary objective of formation control is to maintain desired relative distances among WMRs. This simultaneous coordination in both the lateral and longitudinal directions enables the WMR formation to accomplish complex tasks beyond the capability of a simple collection of individual robots.

Existing research on formation control of WMRs has mainly focused on maintaining a predefined formation, with few studies addressing the problem of transitioning between two formations. For formation maintenance, typical approaches

include leader-follower [5], virtual structure [6], potential-function-based [7], graph-based [8], and behavior-based methods [9]. These methods generally design feedback controllers based on the tracking error between the current and desired formations [10], where the error metrics can be broadly categorized into position-based [6], distance-based [7], [8], displacement-based [5], [11], and bearing-based [9]. These feedback controllers essentially capture the instantaneous spatial coordination among WMRs.

Recently, considering that trajectory tracking control is already quite mature, several studies [10], [11] have attempted to coordinate WMRs at the trajectory level, where spatial positions are optimized over multiple discrete time steps within a fixed time horizon. Nevertheless, these methods still emphasize spatial optimization over a fixed time horizon while paying limited attention to temporal coordination, thereby constraining the spatio-temporal coordination of WMRs. This is feasible for formation navigation in open and obstacle-sparse environments. However, real-world environments are often cluttered and dynamic, making purely spatial optimization

with fixed temporal durations insufficient to handle environmental changes effectively and promptly. These limitations undermine the applicability and adaptability of the aforementioned methods in real-world environments, thus highlighting the need for a joint spatio-temporal optimization framework.

For formation transition, maintaining the current formation is not always feasible in real-world environments. Sudden changes in the navigable area may invalidate the current formation, thus necessitating timely and rapid formation transition to avoid collisions. Such transition involves both lateral and longitudinal coordination among all WMRs, making trajectory conflicts and the resulting collisions highly likely. The extent of such conflicts is directly determined by the assignment of WMRs to target positions. Previous studies [12], [13] typically adopt a decoupled pipeline: a Hungarian-based method is first used to determine the WMR-to-target assignment, followed by A*-based path planning and conflict checking; this process is repeated until all conflicts are resolved and an optimal assignment is obtained. However, the alternation between assignment attempts and conflict checking reduces computational efficiency, thus motivating the development of a more integrated and efficient solution to support timely formation transition when necessary.

In this paper, we focus on continuous formation navigation of WMRs in real-world environments, which aligns more closely with practical task requirements but has received limited attention. Addressing it requires simultaneous improvements in both formation generation and formation maintenance, as well as effective integration between them. Accordingly, as illustrated in Fig. 2, we propose REACT (Real-time Environment-Adaptive architecture for Continuous formation navigation), which consists of two key modules: TCF-R2T (Trajectory-Conflict-Free Robot-to-Target assignment) for rapid formation generation, and JSTP (Joint Spatio-Temporal trajectory Planning) for robust formation maintenance. The main contributions of this paper are as follows.

- 1) Unlike previous studies that mainly focus on tracking pre-defined formations, we propose REACT, an environment-adaptive architecture for continuous formation navigation in real-world environments. REACT leverages centralized formation generation to avoid trajectory conflicts among WMRs during formation transitions, while employing distributed trajectory planning to achieve robust and flexible formation maintenance.
- 2) We propose TCF-R2T, a polynomial-time robot-to-target assignment algorithm for formation generation. By constructing a time-expanded network with conflict-free actions at each step, TCF-R2T avoids the iterative assignment attempts and conflict resolution required by Hungarian-based methods, thus improving computational efficiency and enabling rapid formation transitions.
- 3) We propose JSTP, a joint spatio-temporal trajectory planning method for formation maintenance. Unlike existing studies that primarily optimize spatial positions under fixed time horizons, JSTP simultaneously optimizes spatial positions and corresponding segment durations, effectively enhancing coordination among WMRs and

Fig. 2. REACT architecture for continuous formation navigation of WMRs. Our upper layer integrates global information and centrally generates environment-adaptive, conflict-free formations when necessary, while each WMR in our lower layer continuously maintains the current formation through distributed trajectory planning.

thus improving formation maintenance performance in the presence of obstacles. Moreover, JSTP explicitly incorporates dynamic obstacle avoidance, whereas previous studies primarily consider static obstacles.

The rest of this paper is organized as follows. Section II presents the proposed REACT architecture for continuous formation navigation. Section III introduces the TCF-R2T assignment algorithm for centralized formation generation, while Section IV details the JSTP planning method for distributed formation maintenance. Section V presents comparisons with existing methods, as well as simulation and real-world experiments. Finally, Section VI concludes this paper.

II. OVERVIEW OF THE REACT ARCHITECTURE

This paper aims to develop a flexible and adaptive formation control method for continuous navigation of WMRs in real-world environments. Continuous navigation essentially involves two aspects: maintaining the current formation and performing formation transitions when required by the environment. Accordingly, as shown in Fig. 2, REACT adopts a hierarchical architecture: (1) upper-layer centralized formation generation by the formation manager, and (2) lower-layer distributed trajectory planning by individual WMRs. The formation manager centrally generates environment-adaptive formations when needed, while the WMRs continuously track the generated formation via distributed trajectory planning. Under this architecture, tracking a newly generated formation naturally constitutes a formation transition process. In the following, we first present the mathematical description of the WMR formation, and then introduce the pipeline of REACT.

A. Graph-based Formation Description

Before introducing formation generation and tracking, we first establish the mathematical description of the WMR formation. A formation configuration is composed of two parts: the formation geometry, represented by a set of desired positions, and the robot-to-position assignment, which specifies which WMR is assigned to each position in the formation. The formation of N WMRs is characterized by a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} := \{1, 2, \dots, N\}$ and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$

represent the sets of vertices and edges, respectively. Each vertex $u \in \mathcal{V}$ corresponds to a WMR with position vector $\mathbf{p}_u = [x_u, y_u]^\top$. A directed edge $(u, v) \in \mathcal{E}$ from u to v indicates that WMR v can access the relative distance and trajectory information of WMR u . In this paper, we assume that each WMR can obtain information from all other WMRs. The weight associated with edge (u, v) is defined by the weighted Euclidean distance $w_{uv} = \|\mathbf{W}(\mathbf{p}_u - \mathbf{p}_v)\|_2^2$, where $\mathbf{W} := \text{diag}(a, 1)$ is the weight matrix and $\|\cdot\|_2$ denotes the 2-norm. The parameter a allows certain directions to be prioritized over others when spatial importance varies.

Since the primary objective of formation control is to maintain the desired relative distances among WMRs, we naturally adopt the graph representation matrix, i.e., the Laplacian matrix $\tilde{\mathbf{L}}$, which encodes the relative distances among all WMRs, to characterize the formation. Given the positions $\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_N$, the pairwise edge weights w_{ij} can be computed accordingly. The adjacency matrix is then defined as $\tilde{\mathbf{A}} = [w_{ij}]$, and the degree matrix is given by $\tilde{\mathbf{D}} = \text{diag}(d_1, \dots, d_N)$, where $d_i = \sum_{j=1}^N w_{ij}$. The Laplacian matrix is obtained as $\tilde{\mathbf{L}} = \tilde{\mathbf{D}} - \tilde{\mathbf{A}}$. Therefore, relative positions between WMRs are sufficient for the formation description.

B. Pipeline of REACT

As illustrated in Fig. 2, REACT is a hierarchical architecture. To ensure consistent formation tracking across all WMRs and avoid conflicts during formation transitions, the manager centrally generates formations and coordinates the WMRs, thereby promoting global efficiency. The manager can be deployed either on an external host or on one of the WMRs. Meanwhile, each WMR performs distributed trajectory planning independently, which endows the overall architecture with flexibility and robustness. Consequently, REACT combines the strengths of both centralized and distributed paradigms, maintaining sufficient efficiency while ensuring robustness.

On the manager side, the obtained environmental information is periodically evaluated to determine whether a new formation is needed. Significant changes in the navigable area typically invalidate the current formation and thus trigger formation generation. A geometric formation structure is first generated, followed by a conflict-free robot-to-target assignment. For formation structure generation, we assume that the inter-WMR spacing in the longitudinal (x) direction is uniform and adopt the classical interlaced scheme [13], which offers improved navigation safety. Based on the navigable width, target positions are allocated uniformly and symmetrically across available columns, yielding their relative positions directly. The assignment computation via TCF-R2T is detailed in Section III. Finally, the generated environment-adaptive formation is dispatched to the WMRs for tracking. On the robot side, each WMR executes JSTP to continuously maintain the current formation through joint spatio-temporal optimization, as elaborated in Section IV.

III. TRAJECTORY-CONFLICT-FREE ROBOT-TO-TARGET ASSIGNMENT FOR FORMATION GENERATION

In this section, we present TCF-R2T, which assigns each WMR to a target position in the newly generated formation

Fig. 3. Illustration of the TCF-R2T algorithm. (a) Longitudinally aligned start positions R1, R2 and target positions G1, G2. (b) Undirected graph G constructed from the geometric topology of the start and target positions. (c) Time-expanded network $\mathcal{N}^T$ constructed from graph G . (d) The edge-expansion pattern for each edge in graph G , used to connect vertex copies across multiple time steps in the time-expanded network $\mathcal{N}^T$.

Algorithm 1 TCF-R2T

Input: Robot positions $\mathbf{R}$, target positions $\mathbf{G}$, cost function $c(\cdot)$
Output: Optimal assignment $\mathcal{A}^*$, conflict-free trajectories $\mathcal{T}^*$

- 1: $\mathbf{R}', \mathbf{G}' \leftarrow \text{longitudinal-alignment}(\mathbf{R}, \mathbf{G})$
- 2: $G = (V, E) \leftarrow \text{construct an undirected graph from the geometric topology of } \mathbf{R}' \text{ and } \mathbf{G}' \text{ using linear indexing}$
- 3: $T_{\min} \leftarrow \text{initial time horizon}$
- 4: $T_{\max} \leftarrow \text{estimated upper bound on the optimal makespan}$
- 5: **for** T from $T_{\min}$ to $T_{\max} - 1$ **do**
- 6: $\mathcal{N}^T \leftarrow \text{construct the } T\text{-step time-expanded network from } G \text{ via the edge-expansion pattern with the edge costs given by } c(\cdot)$
- 7: **if** an feasible MCMF solution f_T^* is found in $\mathcal{N}^T$ **then**
- 8: $\mathcal{A}^*, \mathcal{T}^* \leftarrow \text{decode } f_T^* \text{ via inverse linear indexing}$
- 9: **break**
- 10: **else**
- 11: **continue**
- 12: **end if**
- 13: **end for**
- 14: **return** $\mathcal{A}^*, \mathcal{T}^*$

structure and finalizes formation generation, ensuring that all WMRs can transition from their current positions to the assigned target positions without trajectory conflicts. We first illustrate its workflow with an intuitive example and then analyze its computational complexity.

Given a new formation structure, let $\mathbf{R}$ and $\mathbf{G}$ denote the sets of robot and target positions, respectively. For the formation transition from the current formation to a newly generated formation, WMR-to-target assignment aims to minimize the total travel distance while avoiding trajectory conflicts. In particular, column changes should be minimized, since WMRs are nonholonomic and lateral column changes are most likely to induce trajectory intersections and conflicts.

The workflow of TCF-R2T is summarized in Algorithm 1, and an illustrative example is shown in Fig. 3. First, as illustrated in Fig. 3(a), since translation preserves the optimal assignment [14], we align the minimum coordinates of the WMRs and targets along the WMRs' forward direction (x -direction) to remove redundant translational offsets and thus accelerate computation. We then round the coordinates to map the assignment problem onto a grid map. Based on the 4-neighbor geometric topology, we further construct an undirected graph $G = (V, E)$, where vertices V represent the grid points and edges E denote their connections; see Fig. 3(b) for illustration. The vertex index can be computed directly

from its coordinates using linear indexing, i.e., $\text{index} = x + y(\max(x) + 1)$, where the coordinate pair can also be uniquely recovered from the index via inverse mapping. So far, since the WMRs have no specific target preferences, the WMR-to-target assignment problem is transformed into an anonymous MAPF problem on the graph.

The anonymous MAPF problem can be solved in polynomial time using the maximum-flow algorithm [15]. In our case, we further seek to minimize column changes, which requires assigning edge costs and then solving the T -step time-expanded network $\mathcal{N}^T$ shown in Fig. 3(c) via the minimum-cost maximum-flow (MCMF) algorithm. Specifically, the vertices of graph G are duplicated across $2T + 1$ layers, including the initial layer “0 out”, and for each time step t , the beginning layer “ t in” and the ending layer “ t out”. For each edge $(A, B) \in E$, the corresponding copies of A and B in adjacent time layers are connected according to the edge-expansion pattern presented in Fig. 3(d). A “Source” node and a “Sink” node are then added to connect all start and target vertices, respectively, yielding the structure of $\mathcal{N}^T$.

Conflict resolution is achieved by the edge-expansion pattern in Fig. 3(d). In MAPF, motion conflicts consist of edge conflicts and vertex conflicts [16]. We assign unit capacity to all edges. The gray dashed box in Fig. 3(d) resolves edge conflicts, since unit capacities prevent two WMRs from traversing the same edge in opposite directions at the same time. The two cyan edges outside the box resolve vertex conflicts, since unit capacities ensure that at most one WMR can arrive at a vertex at each time step. Since conflicts are resolved at every time step, collision-free trajectories are guaranteed over the entire horizon. For the edge cost $c(\cdot)$, only the purple edge in Fig. 3(d) has nonzero cost: $\Delta x_{\max}$ for motions causing a column change, 1 for motions without column change, and 0 for waiting, where $\Delta x_{\max}$ is the maximum possible longitudinal travel distance. This cost design satisfies our objective of minimizing column changes while also minimizing the total travel distance. After assigning the capacities and costs, we complete the construction of $\mathcal{N}^T$.

The time-expanded network $\mathcal{N}^T$ can be solved in polynomial time using MCMF algorithms with optimality guarantees [17], such as the successive shortest path algorithm. The estimated initial search horizon $T_{\min}$ can be set to 0. The number of MCMF invocations is bounded by $T_{\max}$, whose upper bound is $N + l - 1$, where N is the number of WMRs and l denotes the maximum pairwise distance between $\mathbf{R}'$ and $\mathbf{G}'$ [15]. Since $l = \mathcal{O}(|V|^{1/2})$ in the 2-D grid map, where $|V|$ is the number of vertices, $T_{\max}$ is polynomially bounded. Therefore, TCF-R2T runs in polynomial time. The optimal solution of $\mathcal{N}^T$ is decoded through inverse linear indexing to obtain the optimal conflict-free assignment $\mathcal{A}^*$ and the collision-free grid-based trajectories $\mathcal{T}^*$. The resulting trajectories $\mathcal{T}^*$ are then used to initialize the joint spatio-temporal trajectory optimization in Section IV.

IV. JOINT SPATIO-TEMPORAL TRAJECTORY PLANNING FOR FORMATION MAINTENANCE

In this section, we present the JSTP method executed by each WMR for formation maintenance. We first introduce

Fig. 4. Schematic illustration of the $\mathfrak{T}_{\text{MINCO}}$ trajectory representation parameterized by $(\mathbf{q}, \mathbf{T})$, where $\mathbf{q} = (\mathbf{q}_1, \dots, \mathbf{q}_{M-1})$ denotes the intermediate waypoints and $\mathbf{T} = (T_1, T_2, \dots, T_M)^\top$ specifies the duration of each polynomial piece. $\mathbf{p}_0$ and $\mathbf{p}_f$ are the given initial and terminal points.

the adopted trajectory representation, then formulate the joint spatio-temporal trajectory optimization problem, present the cost function design and gradient derivation, and finally analyze the safety guarantees of JSTP.

A. Trajectory Representation

As illustrated in Fig. 4, we adopt the $\mathfrak{T}_{\text{MINCO}}$ representation [18], a minimum-control-effort piecewise polynomial trajectory parameterization tailored for joint spatio-temporal optimization, which is defined as follows:

$$\begin{aligned} \mathfrak{T}_{\text{MINCO}} &= \{\mathbf{p}(t) : [0, T_\Sigma] \rightarrow \mathbb{R}^m \mid \mathbf{c} = \mathcal{M}(\mathbf{q}, \mathbf{T}), \\ &\quad \mathbf{q} \in \mathbb{R}^{m(M-1)}, \quad \mathbf{T} \in \mathbb{R}_{>0}^M\}, \end{aligned} \quad (1)$$

where $\mathbf{c} = (\mathbf{c}_1^\top, \dots, \mathbf{c}_M^\top)^\top$ denotes the stacked polynomial coefficient vector, $\mathbf{q} = (\mathbf{q}_1, \dots, \mathbf{q}_{M-1})$ denotes the intermediate-point vector with $\mathbf{q}_i \in \mathbb{R}^m$, $\mathbf{T} = (T_1, \dots, T_M)^\top$ denotes the segment duration vector, and $T_\Sigma = \sum_{i=1}^M T_i$ is the total trajectory duration. In particular, $\mathfrak{T}_{\text{MINCO}}$ admits a linear-complexity bidirectional conversion between the two trajectory parameterizations $(\mathbf{q}, \mathbf{T})$ and $(\mathbf{c}, \mathbf{T})$, with the corresponding mappings $\mathbf{c} = \mathcal{M}(\mathbf{q}, \mathbf{T})$ and $\mathbf{q} = \mathcal{W}(\mathbf{c}, \mathbf{T})$ [18].

Since the WMR dynamics can be modeled as a third-order integrator chain, the polynomial degree naturally follows as $n = 2 \times 3 - 1 = 5$. Therefore, for WMRs, $\mathbf{p}(t)$ is a m -dimensional trajectory consisting of M polynomial pieces, with the i -th piece given by

$$\mathbf{p}_i(t) = \mathbf{c}_i^\top \boldsymbol{\beta}(t), \quad \forall t \in [0, T_i], \quad (2)$$

where $\boldsymbol{\beta}(t) = [1, t, \dots, t^5]^\top$ is the natural polynomial basis, and T_i denotes the duration of the i -th piece.

B. Problem Formulation

Before developing the trajectory planning method, it is necessary to first specify the state variables. By employing the kinematic bicycle model, WMRs are differentially flat, with the position (x, y) serving as the flat outputs [19], from which all system states and control inputs can be uniquely determined through their finite-order derivatives. Accordingly, the spatial dimension is given by $m = 2$. By exploiting differential flatness, trajectory planning can be carried out in a low-dimensional smooth trajectory space, thereby effectively accelerating optimization [18].

Accordingly, trajectory optimization is performed directly over the WMR's flat outputs $\mathbf{p}(t) = (x, y)$. We adopt the

spatial variables $\mathbf{q}$ and temporal variables $\mathbf{T}$ of $\mathfrak{T}_{\text{MINCO}}$ as the optimization variables. Together, they uniquely determine a $\mathfrak{T}_{\text{MINCO}}$ trajectory; as shown in Fig. 4. Specifically, the cost function is formulated in the $(\mathbf{q}, \mathbf{T})$ representation with clear physical meaning, while its gradients are derived in the $(\mathbf{c}, \mathbf{T})$ representation, where the polynomial trajectory admits an analytical form. The resulting gradients are then transformed back to the $(\mathbf{q}, \mathbf{T})$ representation for numerical optimization. This is enabled by the bidirectional linear-complexity conversion between these two representations of $\mathfrak{T}_{\text{MINCO}}$ [18].

Finally, in this paper, we directly formulate the joint spatio-temporal trajectory planning problem with the flat outputs of WMRs as an unconstrained optimization problem,

$$\min_{\mathbf{q}, \mathbf{T}} \boldsymbol{\lambda}^\top [\mathcal{P}_{\text{inter}}, \mathcal{P}_{\text{obs}}, \mathcal{P}_{\text{dyn}}, \mathcal{P}_{\text{form}}, \mathcal{P}_{\text{ctrl}}, \mathcal{P}_{\text{time}}]^\top, \quad (3)$$

where the spatial variables $\mathbf{q}$ and the temporal variables $\mathbf{T}$ are jointly optimized, $\mathcal{P}_x$ represents a penalty term in the cost function, and $\boldsymbol{\lambda}$ denotes the corresponding weight vector. Six key factors are simultaneously optimized, including inter-robot collision avoidance ($\mathcal{P}_{\text{inter}}$), obstacle avoidance ($\mathcal{P}_{\text{obs}}$), dynamical feasibility ($\mathcal{P}_{\text{dyn}}$), formation maintenance ($\mathcal{P}_{\text{form}}$), control effort ($\mathcal{P}_{\text{ctrl}}$), and total travel time ($\mathcal{P}_{\text{time}}$). The corresponding penalty can be enforced by assigning a sufficiently large weight. As a unified and integrated formulation, JSTP (3) effectively balances conflicting objectives, especially formation maintenance and obstacle avoidance. Moreover, its unconstrained form enables high-frequency trajectory planning. Compared with optimizing spatial positions within a fixed time horizon, JSTP jointly adjusts both spatial positions and temporal durations, thereby providing stronger spatio-temporal trajectory deformation capability and a larger solution space for handling complex and dynamic environments.

Specifically, the JSTP optimization problem (3) is solved using the L-BFGS algorithm [20], a highly efficient quasi-Newton optimizer. Trajectory planning is performed in a fully distributed manner. To achieve effective collision avoidance among WMRs, each WMR continuously broadcasts its latest planned future trajectory, while simultaneously optimizing its own trajectory based on the latest received trajectories of the others. In addition, continuous-time inequality constraints $g(\mathbf{p}^{(0)}(t), \dots, \mathbf{p}^{(3)}(t)) \leq 0$, such as dynamic feasibility constraints, are converted into finite-dimensional penalty terms by sampling a set of constraint points $\mathbf{p}_i(t_j)$ along the trajectory, where $t_j = j \cdot T_i/K_i$ is the relative time within the i -th polynomial piece and K_i denotes the number of samples for that piece.

C. Cost Functions and Gradients

We then present the cost function design and gradient derivation. Among the six key factors, inter-robot collision avoidance ($\mathcal{P}_{\text{inter}}$) and obstacle avoidance ($\mathcal{P}_{\text{obs}}$) are safety-critical requirements, while dynamical feasibility ($\mathcal{P}_{\text{dyn}}$) is a soft requirement, since final feasibility is guaranteed by the low-layer controller. These three factors are essentially all range constraints, whereas the other three are objectives to be minimized as much as possible. Formation maintenance ($\mathcal{P}_{\text{form}}$) is our primary objective, whereas control effort ($\mathcal{P}_{\text{ctrl}}$)

and total travel time ($\mathcal{P}_{\text{time}}$) are competing objectives entailing an inherent trade-off.

1) *Obstacle Avoidance $\mathcal{P}_{\text{obs}}$* : Obstacle avoidance is critical to safe navigation and involves both dynamic and static obstacles. Previous work has mainly focused on static obstacles, whereas this paper explicitly considers dynamic obstacles. To achieve dynamic obstacle avoidance, penalties are imposed on the trajectory points $\mathbf{p}(t_j)$ whose distance to the obstacle trajectory $\mathbf{p}_{\text{obs}}(\tau_j)$ falls below the safety threshold $d_{\text{thr_obs}}$ at the corresponding global timestamp $\tau_j = \sum_{r=1}^{i-1} T_r + j \cdot T_i/K_i$. Specifically, the pointwise distance metric is defined as

$$d(\mathbf{p}(t_j), \mathbf{p}_{\text{obs}}(\tau_j)) = \|\mathbf{p}(t_j) - \mathbf{p}_{\text{obs}}(\tau_j)\|_2, \quad (4)$$

and the corresponding pointwise obstacle penalty is given by

$$g_{\text{obs}} = \max \{d_{\text{thr_obs}}^2 - d^2(\mathbf{p}(t_j), \mathbf{p}_{\text{obs}}(\tau_j)), 0\}. \quad (5)$$

The obstacle avoidance cost is then obtained by accumulating the pointwise penalties over all sampled points:

$$\mathcal{P}_{\text{obs}} = \sum_{i=1}^M \left(\frac{T_i}{K_i} \sum_{j=0}^{K_i} \omega_j g_{\text{obs}}^3(\mathbf{p}(t_j), \mathbf{p}_{\text{obs}}(\tau_j)) \right), \quad (6)$$

where $(\omega_0, \omega_1, \dots, \omega_{K_i}) = (\frac{1}{2}, 1, \dots, 1, \frac{1}{2})$ are the trapezoidal integration weights. Static obstacles can be regarded as a special case of dynamic ones, for which $\mathbf{p}_{\text{obs}}(\tau_j)$ is constant, and only the nearest obstacle is considered.

For static obstacles, the gradients of $\mathcal{P}_{\text{obs}}$ with respect to $\mathbf{c}_i$ and T_i can be derived via the chain rule as

$$\frac{\partial \mathcal{P}_{\text{obs}}}{\partial \mathbf{c}_i} = \frac{\partial \mathcal{P}_{\text{obs}}}{\partial g_{\text{obs}}} \frac{\partial g_{\text{obs}}}{\partial \mathbf{c}_i} = \frac{\partial \mathcal{P}_{\text{obs}}}{\partial g_{\text{obs}}} \frac{\partial g_{\text{obs}}}{\partial \mathbf{p}_i(t_j)} \frac{\partial \mathbf{p}_i(t_j)}{\partial \mathbf{c}_i}, \quad (7)$$

$$\frac{\partial \mathcal{P}_{\text{obs}}}{\partial T_i} = \frac{\mathcal{P}_{\text{obs}}}{T_i} + \frac{\partial \mathcal{P}_{\text{obs}}}{\partial g_{\text{obs}}} \frac{\partial g_{\text{obs}}}{\partial t_j} \frac{\partial t_j}{\partial T_i}, \quad (8)$$

$$\frac{\partial \mathbf{p}_i(t_j)}{\partial \mathbf{c}_i} = \beta(t_j), \quad \frac{\partial g_{\text{obs}}}{\partial t_j} = \frac{\partial g_{\text{obs}}}{\partial \mathbf{p}_i(t_j)} \dot{\mathbf{p}}_i(t_j), \quad \frac{\partial t_j}{\partial T_i} = \frac{j}{K_i}, \quad (9)$$

where the remaining gradients can be derived easily. For dynamic obstacles, the gradient with respect to T_i additionally needs to account for the global timestamp $\tau_j = \sum_{r=1}^{i-1} T_r + j \cdot T_i/K_i$, which is used to query the obstacle trajectories during ego-trajectory optimization.

2) *Inter-Robot Collision Avoidance $\mathcal{P}_{\text{inter}}$* : Recall that each WMR continuously broadcasts its latest planned trajectory. Under the fully distributed planning framework, the other WMRs are essentially dynamic obstacles. Similarly, penalties are imposed on the trajectory points $\mathbf{p}(t_j)$ whenever their distance to the trajectory points $\mathbf{p}_l(\tau_j)$ of another WMR $l \in \mathcal{R}$ is smaller than the safety threshold $d_{\text{thr_wmr}}$, where $\mathcal{R}$ denotes the set of all other WMRs. The corresponding distance metric and pointwise penalty function are defined as follows:

$$\hat{d}(\mathbf{p}(t_j), \mathbf{p}_l(\tau_j)) = \|\mathbf{E}(\mathbf{p}(t_j) - \mathbf{p}_l(\tau_j))\|_2, \quad (10)$$

$$g_{\text{inter}} = \max \{d_{\text{thr_wmr}}^2 - \hat{d}^2(\mathbf{p}(t_j), \mathbf{p}_l(\tau_j)), 0\}, \quad (11)$$

where $\mathbf{E} := \text{diag}(1, b)$, is the weight matrix and $0 < b < 1$. Due to the nonholonomic nature of WMRs, collision avoidance should be prioritized along the lateral direction (y -direction). Therefore, $0 < b < 1$ is adopted to promote a larger lateral safety clearance.

$\mathcal{P}_{\text{inter}}$ is constructed in the same manner as $\mathcal{P}_{\text{obs}}$ (6), with g_{obs} replaced by g_{inter} and an additional summation over $\mathcal{R}$. Since $\mathcal{P}_{\text{inter}}$ involves the trajectories of other WMRs, the gradient derivation needs to account for both the relative time $t_j = j \cdot T_i / K_i$ along the ego trajectory and the global timestamp $\tau_j = \sum_{r=1}^{i-1} T_r + j \cdot T_i / K_i$ for the trajectories of other WMRs. Owing to the unified cost-function structure, the derivation is identical to that of $\mathcal{P}_{\text{obs}}$.

3) *Dynamical Feasibility* $\mathcal{P}_{\text{dyn}}$: To ensure that the planned trajectory is trackable and supports coordinated motion, dynamical constraints are imposed on the trajectory. Violations of the velocity and acceleration limits are penalized as:

$$g_v = \max\{\|\dot{\mathbf{p}}(t)\|_2^2 - v_{\max}^2, 0\}, \quad (12)$$

$$g_a = \max\{\|\ddot{\mathbf{p}}(t)\|_2^2 - a_{\max}^2, 0\}, \quad (13)$$

where $v_{\max}$ and $a_{\max}$ denote the maximum speed and acceleration of the WMRs, respectively.

For the front-wheel steering constraint induced by the nonholonomic property, the steering angle δ can be obtained from the trajectory curvature κ as $\delta = \arctan(\kappa L)$, where $\kappa = \ddot{\mathbf{p}}(t)^\top \mathbf{M} \dot{\mathbf{p}}(t) / \|\dot{\mathbf{p}}(t)\|_2^3$, L is the wheelbase, and $\mathbf{M} := \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$. To avoid complicated trigonometric computations, the steering constraint is equivalently enforced by bounding the trajectory curvature as $|\kappa| \leq \kappa_{\max}$, where $\kappa_{\max} = \tan \delta_{\max} / L$ and $\delta_{\max}$ is the maximum front-wheel steering angle. The corresponding pointwise penalty is defined as:

$$g_\delta = \max\{\kappa^2 - \kappa_{\max}^2, 0\}. \quad (14)$$

The feasibility penalty $\mathcal{P}_{\text{dyn}}$ is formulated similarly to $\mathcal{P}_{\text{obs}}$ in (6), where g_{obs} is replaced by $(g_v + g_a + g_\delta)$.

4) *Formation Maintenance* $\mathcal{P}_{\text{form}}$: As described in Section II-A, the WMR formation is characterized by the Laplacian matrix $\tilde{\mathbf{L}}$. Therefore, we define the following formation error metric f_e based on the difference between the current and desired Laplacian matrices to quantify the deviation of the current formation from the desired one:

$$f_e = \|\tilde{\mathbf{L}} - \tilde{\mathbf{L}}^*\|_F^2 = \text{tr}\{(\tilde{\mathbf{L}} - \tilde{\mathbf{L}}^*)^\top (\tilde{\mathbf{L}} - \tilde{\mathbf{L}}^*)\}, \quad (15)$$

where $\text{tr}\{\cdot\}$ denotes the trace operator, $\|\cdot\|_F$ denotes the Frobenius norm, and $\tilde{\mathbf{L}}$ and $\tilde{\mathbf{L}}^*$ are the Laplacian matrices characterizing the current and desired formations, respectively. Differentiable f_e can be directly incorporated into the optimization. The formation penalty is then defined as $g_{\text{form}} = f_e(\mathbf{p}(t_j), \{\mathbf{p}_l(\tau_j)\}_{l \in \mathcal{R}})$, where $\mathcal{R}$ denotes the set of all other WMRs, and $\tilde{\mathbf{L}}$ is computed from these positions as described in Section II-A. $\mathcal{P}_{\text{form}}$ is then obtained by replacing g_{inter} in $\mathcal{P}_{\text{inter}}$ with g_{form} . The gradients of $\mathcal{P}_{\text{form}}$ with respect to $\mathbf{c}_i$ and T_i follow the same derivation as those of $\mathcal{P}_{\text{inter}}$.

5) *Control Effort* $\mathcal{P}_{\text{ctrl}}$: The control effort is directly measured by the integral of jerk, which is directly differentiable and inherently serves as a trajectory smoothness cost.

6) *Total Time* $\mathcal{P}_{\text{time}}$: The travel time cost is directly given by $\mathcal{P}_{\text{time}} = \sum_{i=1}^M T_i$. Since time is an independent parameter in $\mathcal{T}_{\text{MINCO}}$, the gradients can be directly derived as $\partial \mathcal{P}_{\text{time}} / \partial \mathbf{c}_i = \mathbf{0}$, $\partial \mathcal{P}_{\text{time}} / \partial T_i = 1$.

TABLE I
RUNTIME (ms) COMPARISON UNDER DIFFERENT FORMATION SIZES

Formation Size	8	16	18	20	22	24	26	28	30
Hungarian-Based [13]	28.4	26.7	36.5	37.6	48.2	43.4	59.4	55.5	75.0
TCF-R2T (Ours)	0.7	4.4	5.0	8.7	9.1	14.8	15.4	22.8	24.3
Reduction (%)	97.4	83.5	86.4	76.9	81.2	66.0	74.0	58.9	67.6

D. Safety Design

We adopt the following designs to support safe formation navigation: (1) Conflict-free upper-layer generation: The formation generated by the upper layer ensures conflict-free robot-to-target assignments, thereby eliminating potential trajectory conflicts during formation transition. (2) High-frequency planning: Trajectory planning runs at 20 Hz to promptly respond to sudden environmental changes. (3) Prioritized collision avoidance: The collision-avoidance terms ($\mathcal{P}_{\text{obs}}$ and $\mathcal{P}_{\text{inter}}$) are assigned the highest weights, one order of magnitude larger than the others, making them the top priority in optimization. (4) Explicit safety verification: Optimized trajectories are sent to the controller only after passing an explicit collision check. (5) Indirect safety via formation constraints: The formation maintenance cost enforces desired inter-WMR distances, providing an indirect safety guarantee; trajectory interactions among WMRs are involved in both $\mathcal{P}_{\text{inter}}$ and $\mathcal{P}_{\text{form}}$. (6) Ultimate safety fallback: An independently operating Autonomous Emergency Braking (AEB) module is triggered when the time-to-collision (TTC) with obstacles or other WMRs falls below a preset threshold.

V. EXPERIMENTS

In this section, we first present comparative results on formation generation efficiency and formation maintenance performance. We then demonstrate the effectiveness and practical applicability of REACT through both simulation and real-world experiments. Experimental videos are available on the [project website](#).

A. Formation Generation Efficiency

The efficiency of formation generation is directly determined by the computational speed of conflict-free assignment, since formation structure generation is straightforward. Here, we compare the runtime of TCF-R2T and the classical Hungarian-based method [13] for computing conflict-free assignments across different formation sizes, ranging from 8 to 30 WMRs. The scenario involves a formation transition from four columns to two columns caused by changes in the navigable area. The results are summarized in Table I, which shows that TCF-R2T reduces the runtime by at least 55% across all formation sizes. This improvement is attributed to the constructed time-expanded network, which resolves action conflicts at each time step and thus enables the optimal assignment to be computed directly. In contrast, Hungarian-based methods [13] require iterative processes of assignment attempts and conflict resolution.

Fig. 5. Comparison of formation maintenance performance. (a) Experimental scenario, where seven WMRs are uniformly arranged in an interlaced three-column formation, and two consecutive obstacles are placed ahead. (b) Experimental results, which demonstrate that our method achieves the best formation maintenance performance under consecutive obstacle disturbances.

B. Formation Maintenance Performance

We compare our JSTP with methods that can simultaneously handle formation maintenance and obstacle avoidance, including the behavior-based method with unit-center reference [9], the Control Barrier Function-Quadratic Programming (CBF-QP) [21], and JSTP-Spatial, a reduced version of our JSTP method that optimizes only the spatial parameters. Considering the scenario shown in Fig. 5(a), a seven-WMR formation arranged in three columns encounters two consecutive obstacles: one located between two columns and the other directly in front of the third column. This scenario constitutes a basic unit of obstacle-rich environments. The formation error metric f_e is adopted for comparison, and the symmetrically normalized Laplacian matrix is used to eliminate the influence of spatial scale. The results are presented in Fig. 5(b), which demonstrate that our method achieves the best formation maintenance performance and stability under consecutive obstacle disturbances. Specifically, the maximum formation error is reduced by 75% compared with the behavior-based method and by 64% compared with CBF-QP. Moreover, compared with JSTP-Spatial, JSTP achieves a further 13% reduction, which highlights the necessity of joint spatio-temporal optimization.

C. Simulation and Real-World Experiments

To demonstrate the practical effectiveness of REACT, we conduct experiments on formation convergence, obstacle avoidance, and formation transition in both simulated and real-world environments. The complete experimental results are available on the [project website](#), and representative results are presented below. Specifically, Fig. 6 shows snapshots of formation navigation in an obstacle-rich environment, where each WMR independently perceives obstacles using simulated

LiDAR. The WMRs timely and effectively avoid surrounding obstacles under complex environmental constraints, while maintaining satisfactory formation performance. This experiment demonstrates the strong spatio-temporal coordination capability of JSTP and its effectiveness in balancing multiple conflicting objectives in complex environments.

In the real-world experiments, seven Ackermann-steered WMRs ($0.22 \text{ m} \times 0.19 \text{ m} \times 0.13 \text{ m}$) are deployed in a $9 \text{ m} \times 5 \text{ m}$ area. Markers attached to the WMRs and obstacles enable precise pose tracking via the FZMotion motion capture system, while real-time speeds are measured by onboard sensors. Each WMR independently perceives the environment using its onboard LiDAR. In addition, each WMR broadcasts its latest planned future trajectory and communicates with the formation manager running on an external host via Robot Operating System (ROS) messages. Specifically, as shown in Fig. 7, the WMR formation successfully avoids the dynamic obstacle while maintaining satisfactory formation performance, and then quickly converges back to the desired formation. Fig. 8 illustrates the formation transition process. As the navigable area decreases, the WMR formation promptly transitions from three columns to two columns without trajectory conflicts and then smoothly returns to three columns after passing through the narrow area. These experiments demonstrate the practical feasibility of REACT for real-world deployment.

VI. CONCLUSION

In this paper, we propose REACT, a hierarchical architecture for continuous formation navigation of WMRs in real-world environments. It consists of centralized conflict-free formation generation and distributed robust formation maintenance. Specifically, we first design TCF-R2T for rapid conflict-free WMR-to-target assignment, enabling timely formation transitions without trajectory conflicts. We also develop JSTP to jointly optimize spatial positions and temporal durations, thereby enhancing coordination among WMRs and improving formation maintenance performance under obstacle disturbances, including dynamic obstacles. Comparative results demonstrate the advantages of our proposed methods, while simulation and real-world experiments validate the effectiveness and practical applicability of REACT.

In the future, we plan to integrate the generalizable understanding and reasoning capabilities of large language models (LLMs) into the REACT architecture to further improve its environmental adaptability, particularly in the formation generation stage. We also intend to deploy and evaluate REACT in a broader range of environments, such as scenarios with structured road constraints and complex mountainous terrains with significant elevation changes. Finally, we are also interested in extending REACT to other robotic platforms, such as unmanned aerial vehicles (UAVs).
